The Philadelphia Medical Journal

A Weekly Journal Owned and Published by The Philadelphia Medical Publishing Company and Conducted Exclusively in the Interests of the Medical Profession

JAMES HENDRIE LLOYD, A.M., M.D., *Editor-in-Chief*

JULIUS L. SALINGER, M.D., *Associate Editor*

Assistant Editors

JOSEPH SAILER, M.D.

F. J. KALTEYER, M.D.

D. L. EDSALL, M.D.

T. L. COLEY, M.D.

J. M. SWAN, M.D.

W. A. N. DORLAND, M.D.

J. H. GIBBON, M.D.

Scientific Articles, Clinical Memoranda, News Items, etc., of interest to the profession are solicited for publication. Reprints (250) of Original Articles will be furnished gratis to Authors making the request.

The Editorial and Business Offices are at 1716 Chestnut St. Address all correspondence to

The Philadelphia Medical Journal, 1716 Chestnut St., Philadelphia, Pa.

See Advertising Pages 8 and 36.

VOL. VII, No. 1

JANUARY 5, 1901

\$3.00 PER ANNUM

Salutatory.—With the present number the PHILADELPHIA MEDICAL JOURNAL appears under new editorial management. The occasion is not one that calls for extended comment. It may be proper to state, however, that the present editor is not entirely new to the task, as he has been a frequent, almost constant, contributor to the editorial pages of the JOURNAL from its inception. In this work he has devoted his pen to the more strictly scientific aspects of medicine as they have been discussed here. The change in editorial supervision does not necessarily indicate any radical change in the general scope, appearance, and scientific aims of the JOURNAL. What changes, if any, may occur will be the results of careful forethought and for the best interests of our readers. In the future, as in the past, the object will be to present a high class of original papers, to reflect faithfully the most useful contemporary literature, and to relate weekly the most important events in the medical world. These editorial columns will be kept exclusively for the discussion of subjects that are purely professional. It is due to the host of readers, subscribers, and contributors, who have made this JOURNAL a success in the past, that acknowledgment should be made here now of their support, and that they should be assured that no effort will be spared in the future to make the JOURNAL a reflex of their interests and their views, as well as a fitting exponent of one of the most important centers of medical learning in America.

The Medico-Legal Relations of the X-ray.—A great danger attending the introduction of new methods of diagnosis is that the most recent procedure may be endowed by its advocates with more than its proper share of weight as evidence. With admirable foresight, the American Surgical Association has anticipated this contingency and, at the meeting held in 1897, appointed a committee, of which Dr. J. William White was chairman, to report upon the medico-legal relations of the x-rays. This committee made a report at the Washington meeting held in May, 1900 (*American Journal Medical Sciences*, July, 1900). The facts collected by the committee go to show that there have already been cases of improper use of the skiagram in court and that there is a real danger for the future from the teaching of some members of the profession, who have exalted skiagraphy beyond its present merits. Grave mistakes have been

made in reference to the presence or absence of fractures, one of the most striking of which is the failure of a skiagram to show the line of fracture after complete osteotomy, only 24 hours old. Defective plates may lead to errors concerning foreign bodies; in one instance such a defect was considered to indicate the existence of a renal calculus. It is thus shown that the x-rays are not infallible and that in addition to the skiagram the surgeon should employ the methods which experience has shown to be trustworthy in drawing his conclusions in a given case. There seems to be no justification for the teaching that x-rays should be employed as a routine method of examination in every case for the diagnosis of fractures. Indeed, in the region of the base of the skull, the vertebral column, the pelvis, and the hips, the results are far from satisfactory. Again, it should be remembered that a skiagram alone is very misleading with regard to the existence of deformity. Furthermore, after a recent fracture an x-ray examination will not be sufficient to prognosticate union or nonunion with accuracy. The investigations of the committee seem to show that while x-ray burns are, in the majority of cases, easily preventable, their cause is not definitely known. The skiagram has already been admitted as evidence in medico-legal cases and its use will undoubtedly increase; it is necessary, therefore, that its sources of fallacy should be borne in mind. The surgeon should familiarize himself with the appearances of skiagrams, with their distortions, with the relative values of their shadows and outlines so that he may judge of their teachings and not be dependent upon the interpretations of others. The conclusions of the committee were wisely adopted unanimously by the members as expressing the views of the American Surgical Association. The association, by this action, while setting forth the advantages of x-ray examinations, avoids the fallacy of giving to skiagrams more than their proper relative importance.

Gastrointestinal Autointoxication.—Weintraub stated in Lubarsch and Ostertag's "Ergebnisse," that most cases reported as instances of gastrointestinal autointoxication bear absolutely no resemblance to such a condition except in the name given them. There is certainly much more scientific truth in this brief remark than in most of the more elaborate writings con-

cerning the subject. The publication of Bouchard's book, followed by Altru's and other somewhat elaborate works, produced a swarm of smaller articles which buzzed about one's ears so industriously that many a poor doctor seems to have concluded that there is justification for considering every case of obscure disease the result of poisoning from the alimentary tract. If only there is some evidence of disturbance of the stomach or bowels, or if treatment which is likely to relieve disease of these organs produces improvement the diagnosis becomes clear at once—and the treatment should evidently be to disinfect the gastrointestinal tract by drugs or mechanical means until the source of the noxious thing is removed. Such wild enthusiasm was born of the very originators of the discussion. In order to prove the doctrine they taught they looked in but one direction. The reactive party has now begun to show its head. Gumprecht has pointed out that there is little or no real demonstration of the existence of poisoning from the stomach, and authorities like Ewald and Robin have stated only recently that there has been far too free a use of the term gastrointestinal auto-intoxication and that even clinical evidence of its occurrence is scanty and rarely found, and the profession in general has begun to pause and deliberate before giving itself over to such a diagnosis.

Nevertheless there is a conviction in most reasoning minds that a not inconsiderable number of cases show signs of self-poisoning, and that in many of these cases the gastrointestinal tract apparently bears a close relationship to the production of the symptoms, though a clear recognition of the actual fault is difficult to reach.

The most satisfactory proof of the accuracy of a thought that must have been in many minds—that these cases should be considered to be due to general metabolic abnormalities rather than to simple digestive derangements—has been provided lately by Strauss and Philippsohn (*Zeitschrift für klinische Medizin*, Band xl, Hefte 5 and 6). After a laborious and elaborate study they conclude that there is in the first place excellent evidence that normally the products of intestinal putrefaction, while absorbed in considerable amounts, appear in the urine in only small quantities. They have in large part been, therefore, so altered by the tissues that their products which appear in the urine are harmless and are no longer recognizable as the products of putrefaction. Further, while one may in some conditions, often thought to be intoxications from the gastrointestinal tract, find abnormally large amounts of volatile fatty acids, ethereal sulphates, and other substances produced by putrefaction in the alimentary tract, there is usually no evidence that these substances are actually produced or absorbed in excessive quantities. There are many important details in the article, but the main point is indicated by what has been stated, *i. e.*, in a large number, probably a *very* large number,

of cases thought to be gastrointestinal intoxication, we should rather speak of a *tissue intoxication*. In other words, the gastrointestinal tract may be producing only a normal amount of toxic material, perhaps less than normal, or possibly a little more than normal. The tissues are, however, unable to cope with even normal amounts, and intoxication results.

The moral from all this story is that we have been too narrow in our views, and that the subject is far less easy than we have been led to believe. Such patients cannot be cured by mere colonic flushings or gastric lavage: they can be cured only as can persons with other metabolic abnormalities, by painstaking control of all the details of their lives, not of those alone which relate solely to the alimentary tract.

The Diagnosis of Mitral Stenosis.—The condition of mitral stenosis has given rise to a great diversity of opinion among medical authors; both as to its diagnostic features and its pathology. In consulting a large number of well-known works we have been impressed with the inadequacy of many of the descriptions for general application. They have no doubt fitted certain cases, but the various phases of the condition demand recognition and lucid explanation, which is too rarely attempted. First, the pathology demands our attention. We find it stated unequivocally by some writers of great clinical experience that the left ventricle is always atrophied in mitral stenosis, as we should expect it to be theoretically. Others hold that the left ventricle is normal in this condition; and that if atrophy is found, it is not dependent upon the mitral stenosis. This latter view, based as it is upon the extensive study of careful postmortem records, we believe to be the most acceptable and conclusive. There is no marked difference of opinion as to the other pathological processes found.

Discussing the character of the murmur, we find it stated generally, that it is presystolic in time with its point of greatest intensity a little above and within the apex-beat, or at the apex-beat itself; and that it is not transmitted. We have even seen it stated, however, that it may be transmitted towards the sternum; again, and unquestionably this is true, that it is sometimes heard at the left anterior axillary line, sometimes high up in the axilla, and has been heard posteriorly as far as the posterior axillary line. Another writer points out that there are three sets of cases to be considered; one, in which there is a diastolic murmur; another, in which the murmur is undoubtedly presystolic; and a third, in which no murmur whatever is audible.

All the authors consulted note the characteristic thrill, the *fremissement* of Laennec, but we are cautioned that the murmur may be absent in one-third of the cases and that the thrill may be felt, at times, when the murmur is not appreciable. Again, it has been pointed out, and proven conclusively, that the presys-

toxic murmur is not absolutely pathognomonic of mitral stenosis, but is heard in other valvular defects.

As to the characteristics of the murmur there is a unanimity of opinion. It is loud, prolonged, and of a grinding, churning character. For the most part, just prominence is laid upon the accentuation of the second sound, both over the pulmonary area and at the apex, but many authors fail entirely to mention the reduplication of the second sound which is sometimes present—the *bruit de rappel*, or three-toned rhythm of the heart, a condition in which a single systolic sound is followed by a double diastolic sound.

The pulse is passed over in many works with too great brevity. By some it is stated that it may be regular and normal in frequency; by others, that it is of normal rate and irregular; again, that it is irregular and frequent. We may attempt to rationalize this by stating that, early in the disease, with compensation established, there may be no alteration in character or rate. The constant factors to be heeded are the "smallness, softness, and emptiness" of the pulse. Later in the disease its characteristics are its irregularity and frequency.

It would puzzle a student sorely to diagnose correctly many cases of mitral stenosis from some of the descriptions given. The cases are so varied in character, and so often atypical, that we believe more stress should be laid upon diagnosis by exclusion. We should notice especially the enlargement of the right heart, the character of the murmur, and thrill, when present; the character of the pulse, and the familiar picture of easily disturbed equilibrium of the circulation. No less important is the accentuation of the second pulmonary sound and frequent reduplication of the second sound.

In conclusion, it would seem that much of the diversity of opinion among medical writers upon the cardinal points of diagnosis and pathology is due to the fact that current works have been utilized too freely without modifying carefully the opinions expressed by more extensive personal observation, and a careful study of the results of contemporary original research.

By these methods alone, we believe, can a harmony of diverse views and the exclusion of error be brought about.

The Stethoscope Up to Date.—Since 1819, when Laennec first gave to the world the stethoscope, after he had already acquired such a degree of proficiency in its use that he was able to define very closely its advantages and limitations, physicians have been listening to the secrets of diseased processes that had hitherto been so zealously guarded by nature.

It is true that there were many men, such as Clarus, professor of medicine at the University of Leipsic, who until the year of his resignation in 1847 fought against

the methods of physical diagnosis, and refused to introduce them into his courses; but the medical world at large was soon convinced of their extraordinary value, and accepted them with enthusiasm, perhaps a little excessive. Nevertheless, it is surprising that in spite of the complexity of the subject, comparatively so little has been added to the observations of Laennec and his immediate followers, particularly Skoda. On the other hand, the mechanical ingenuity of physicians and instrument makers has been exercised to the utmost in the production of various forms of apparatus which are designed either merely for the purpose of sale to those desiring a novelty, or because the makers believe that they in fact possess some points of superiority over other instruments for similar purposes, and yet it can be said that the single stethoscope, perhaps a trifle lighter and more convenient than the clumsy wooden apparatus employed at first, but not greatly better as a machine for the conducting of sounds, still holds its preeminence. For 40 years it held undisputed sway; then an Englishman, Walter Bryan, introduced a flexible rubber-tube between the funnel and the air-piece, and from this it was but a slight step to the binaural stethoscope.

In the sixth edition of "Abhandlung über Perkussion und Auscultation," Skoda records that "the best form of the stethoscope and the material of which it is constructed is a subject of particular anxiety for those who are not yet accustomed to auscultation," for even in that day the number of stethoscopes, microphones, stethophones, etc., was legion, and the poor student seeking the best instrument was confused with such a mass of advice that he was thoroughly puzzled; and yet, Skoda, in this sentence, implies, as he elsewhere states explicitly, that it makes very little difference what instrument is used, provided that the ear at the farther end is educated to perceive the sounds. To one who listens for the first time, the whirl of noises heard over the heart, or in the chest, sounds hopelessly confused. It is only by prolonged practice that the ability is gradually acquired to disregard all but certain particular sound-waves, and to analyze each in regard to its time, duration, and regularity with accuracy.

It is a curious fact, that so many men who are familiar with auscultation insist that that instrument that conveys the sounds most loudly to the ear is therefore the best. Even Laennec, sharp auscultator as he was, was more or less addicted to this opinion, and in the latest American book upon physical diagnosis, that of Cabot of Boston, the same mistaken idea is apparently held, for in his enthusiastic commendation of the Bowle's stethoscope, he says that the sounds conducted through any one of the 12 tubes in the multiple form are "as loud as those to be heard with a single instrument of the ordinary form, although far fainter than those to be heard with a single Bowle's stethoscope." Sahli, whose work Cabot probably consulted, is much

more correct upon this point; it is not the intensity, but the differentiation of the sounds that is important.

Any one familiar with the use of the microscope will readily appreciate the disadvantage of using a high eyepiece with an inferior lens; the field is blurred, although the image is large. It is the same with the stethoscope that conveys the sounds loudly; they are blurred and indistinct, and it is often impossible to differentiate them satisfactorily. It is for the reason of definition therefore, that differences exist in stethoscopes, and that the advice given by some clinical teachers is to our mind incorrect. It is not sufficient to become acquainted with one form of stethoscope, for murmurs may be heard with one and not with another, as we have often been able to prove to our own and others' satisfaction; but each man should be trained carefully in the movements of the single and double stethoscopes, and immediate auscultation; for it is the ear and not the instrument that does the work.

Nerve Regeneration; Neurotropism.—The regeneration of nerves is an interesting biological phenomenon. Physiologists, pathologists, neurologists, and surgeons have all given attention to it, but despite their combined efforts many phases of the process are still obscure. That severed nerves can reunite, with return of conductivity, is a fact firmly established by physiological and pathological evidence.

It is, furthermore, definitely known that such union can only be brought about by the regeneration of nerve fibers, although a partial restoration of function seems to be possible before an actual new production of nerve fibers has taken place.

This is shown in the occasional disappearance of an old paralysis within a few hours after a surgical operation in which the cut ends of the nerve are accurately brought into apposition.

Regarding the histogenesis of new fibers two theories have been advanced, called the theories of continuous and of discontinuous regeneration respectively. According to the first the new fibers are formed by a down growth of the old axis cylinders; according to the latter the axis cylinder develops by a process of differentiation of undifferentiated fibers that grow from the central stump.

No unequivocal proof of either theory has been of benefit. Whichever be true, the fact remains that the new fibers come from the old fibers of the proximal end.

The steps in the new formation are quite well known, thanks to the labors of Ranvier, Vanlair, Huber, Stroebe, and others. But there is another point at issue, namely, the nature of the force or forces that govern the direction of growth. Why does the central end seek to connect with the peripheral? Ranvier and Vanlair were of the opinion that the governing force was mechanical, that the nerve grew toward the peripheral

end because, owing to the gap, it was the path of least resistance. Many facts favor this theory, but others are against it. With the view of determining the significance of the mechanical factor and the possible cooperation of others, Forssman undertook a very clever series of experiments, the upshot of which is that the *mechanical factor is subordinate*, and that there is another far more potent. For the purpose of more readily controlling the course of the nerve fibers, Forssman employed tubes of straw or collodion. The ends of the cut nerve were either introduced into the upper end and lower parts of the tube respectively, or the proximal was introduced into the upper part, while the distal end was carried along the outside of the tube and by means of an intercalated segment doubled over the top of the tube so as to lie parallel with the central stump. By means of fixation threads the cut ends were retained in place. After a period of two months the animals were killed, the nerves excised, fixed in Müller's fluid, cut into vertical serial sections, and stained by the Weigert-Pal method.

It was found that the growth of new fibers occurred by no means necessarily in the direction of least resistance. If, *e. g.*, the proximal end of the nerve was placed in the tube and the peripheral end carried along the outside to the top, a piece of resected nerve affixed to it, and then turned into the tube so as to lie alongside of the central end, the new nerve fibers growing out from the latter were at first directed peripherad into the tube; but after proceeding thus for a short distance, they doubled upon themselves and grew toward the center, so as to meet the distal end, or the intercalated segment hanging into the tube from above. If only the upper end was placed in the tube, the distal portion of the nerve being entirely removed, almost no growth occurred down the tube, although, mechanically, there was no obstacle. The distal end of the nerve in some way exerts an attraction upon the newly-forming fibers and these respond by growing toward it along the shortest path. The fixation thread has but little influence in guiding them. In one experiment the tube of straw was filled with brain substance, and the proximal end of the tibial nerve carried down along the outside of the tube to the lower end and then fastened. The distal portion of the tibial nerve had been excised as far as its entrance into the calf-muscles. On examination remarkable results were noted—while many new fibers had gathered on the outside of the tube, comparatively few had grown downward, although the muscle interstice of the old nerve was open. On the other hand, a large bundle extended upward into the tube as far as its top. When in control experiments the tube was left empty, very few fibers grew into it, and then only for a short distance.

If the mechanical principle were the guiding one it would be natural to expect a more luxuriant growth under the latter than under the former conditions. As

we have seen, the contrary obtained, and therefore evidently nerve substance possesses some peculiar attractive force which determines the direction of growth in the newly-formed nerve-fibers. This force is akin to that known as chemotropism or chemotaxis, and is therefore designated by Forssman as *neurotropism*. In its essence it is probably also chemical.

In a more recent series of experiments, Forssman endeavored to determine the relative influence upon the central end of a nerve as compared with that of its own peripheral end. He divided the peroneal and tibial nerves, and reunited them in the control animals, while in others he joined central tibial with peripheral peroneal, and vice versa. No difference was found. The central end of the tibial neurotized the peripheral end of the peroneal as nicely as it did its own distal stump. Even if a segment of nerve, as of the peroneal, was interposed between the cut ends of the tibial, the result was the same. When the interpolated nerve came from another animal than a rabbit, as from guineapig, pigeon, or frog, no downgrowth of new fibers occurred. If the ends were left apart, and united only by a cotton thread, the distal end was freely neurotized, and if a piece of rabbit's sciatic was interpolated, the neurotization was abundant. It would thus appear that the nerves of other animals exerted a negative neurotropism on the nerve-fibers of the rabbit. However, it is not wise to generalize too broadly from these few experiments.

Forssman also tested the neurotropic power of spleen and liver, placing emulsions of these organs in the tubes, as in the experiment with brain substance. No growth of fibers took place, showing that the neurotropic substance was absent.

The experiments which we have cited possess a deep significance, apart from their histogenetic importance. They constitute another illustration of that widespread force, at present called chemical, which brings about phenomena that by the old philosophy were considered manifestations of a *vital* force. Neurotropism and chemotropism, to be sure, do not solve the mystery, they only remove one of the many enshrouding veils. The new century will tear off others, but will bequeath the problem still unsolved to a future age.

Sewage is a Fertilizer for Seaweed.—Dr. Letts, the professor of chemistry at the Belfast College (Ireland), has discovered that seaweed is a valuable test for ascertaining the presence of sewage in sea water. Investigations proved that the successful growth of the weed depends almost entirely upon the presence of sewage in the water. The greater the pollution, the more prolific was the growth of the weed, while, on the other hand, if no pollution of the water existed, the weed simply died. It should be understood that these observations were made on the seaweed and sewage near Dublin and Belfast. In other latitudes, other factors might prevail.

Reviews.

Lessons on the Anatomy, Physiology and Hygiene of Infancy and Childhood for Junior Students.

Consisting of Extracts from Lectures given at the Rush Medical College. By ALFRED C. COTTON, A.M., M.D. Chicago: Chicago Medical Book Co. \$1.50.

This will be an extremely useful book for those who are students of medicine, in the catalog sense. Practitioners have in their larger books of reference practically all that is in this condensed work, but perhaps not so conveniently put together. The lack of accurate proof-reading renders it difficult at times for the reader to keep his mind on the subject-matter. If the book represents a required course in pediatrics for all the students in the Rush Medical College, they and the College, as well as the future clientele of the embryo physicians, are to be congratulated on the just importance attached to this hitherto neglected branch of medicine.

The Microtometist's Vade-Mecum. A Handbook of the Methods of Microscopic Anatomy. By ARTHUR BOLLES LEE. Fifth Edition. Philadelphia: P. Blakiston's Son & Co. 1900.

This book needs no introduction to anatomists and zoologists; and to others unacquainted with it, the mere fact of a fifth edition is in itself a sufficient recommendation.

In the preface to this edition the reader is informed that the work has been extensively revised; many old methods have been rejected to make room for many new methods; fuller consideration has been given to the philosophy of cardinal general methods; the chapter on cytologic technic has been in the main rewritten. Of especial interest is the discussion of the principle of precipitation in the process of fixation, based on Fischer's theory that "the coagulation which constitutes fixation is, in the case of the liquid and semi-liquid constituents of tissues, *always* a phenomenon of *precipitation*." Recalling the author's previous emphatic support of Flemming's opinion on the action of potassium bichromate on kinetic chromatin, which he said gave "merely unnatural caricatures of the true structures," it is interesting to note, in the section on cytologic fixing agents (p. 360), that now he regards some of the chromatin images given by this reagent as more lifelike than when produced by acids.

As always, the book is a treasure-house of information and suggestion.

Egbert's Hygiene and Sanitation. A Manual of Hygiene and Sanitation. By SENeca EGBERT, A.M., M.D., Professor of Hygiene in the Medico-Chirurgical College of Philadelphia. New (2d) and revised edition. In one handsome 12mo volume of 427 pages, with 77 engravings. Philadelphia and New York: Lea Brothers & Co. Cloth, \$2.25 net.

This manual is a welcome addition to the limited number of exact and satisfactory handbooks on hygiene. To incorporate 14 distinct subdivisions of this important subject in a 12mo volume of 427 pages, allotting sufficient reading matter, that each division may be of practical use, and to do it as well as the author has done, is most gratifying. The new chapter on Military Hygiene is a necessary and welcome addition. Could the suggestion contained therein have been applied practically during the past few years, many of our soldiers' lives would undoubtedly have been spared. In connection with this chapter we feel that the author has not emphasized sufficiently the value of fire as a purifying and destructive agent for camp offal. Practically it has been found that even the simpler forms of chemical disinfectants are not always obtainable, and to secure their proper use in camp is a seeming impossibility. To disinfect properly the contents of pits and sinks and then cart away, requires so much detail that it will be impossible to have it performed without the most constant watchfulness. The New York State militia have in practical use a privy on wheels in which all discharges from the men are consumed by fire without the necessity of handling, and as it accompanies the men even on the march, the danger of spreading infection beyond camp limits is reduced to a minimum. In Santiago

and elsewhere cremation has superseded very largely chemical disinfection, and in every case where cremation is at all practicable it should be used in preference to other more uncertain and troublesome methods. We refer to the destruction of camp refuse and not to the disinfection of clothing, bedding, etc. To the country physician and to those without access to the larger works this book will be found especially useful, and we trust it may have a sale commensurate with its unquestionable value. Every rural health officer should possess a copy.

Textbook of Physiology. Edited by E. A. SCHÄFER, LL.D., F.R.S., Professor of Physiology, University of Edinburgh. Vol. II. New York: The Macmillan Co. 1900.

In a notice of the first volume of this noteworthy textbook of modern physiology, published in the PHILADELPHIA MEDICAL JOURNAL, Vol. I, page 906, it was stated that the scope of the work is different from that of any similar work in English, comparable only to Hermann's Handbook—that is to say it is a systematic arrangement of the whole sphere of physiologic facts and doctrines presented in their proper connection and just proportion and verified by that copious citation of original sources which is so indispensable to the advanced student, teacher, and original investigator.

The second volume, comprising some 1300 pages, has just been published and in its general make-up maintains the high standard set by the first volume. The articles are written by physiologists whose names are a sufficient guarantee for scientific accuracy, thoroughness, and philosophic presentation. It is safe to say there is hardly any phase of modern physiology that does not receive complete and elaborate treatment. Each article is not only a resumé of all that has hitherto been published in works of similar character, but is a thorough presentation of the results of investigations the world over during the past 20 years. Though this textbook will appeal most strongly to professional physiologists and teachers, yet the practical character of the articles and their bearing on all problems of clinical medicine will commend it to teachers and practitioners of clinical medicine as well. In no other work can there be found such a wealth of facts and observations of a practical character.

In a brief notice of a work so extensive as this nothing but an enumeration of the table of contents is possible. The papers have reference mainly to the mechanisms of the circulation, respiration, the functions of the central nervous system, the general physiology of muscle and nerves, the special senses, etc. The table of contents is as follows:

The Mechanism of the Circulation of the Blood. 166 pages. By Dr. Leonard Hill.

The Contraction of the Cardiac Muscle. 60 pages. By W. H. Gaskell.

Animal Mechanics. 46 pages. By I. B. Hayercraft.

The Muscular and Nervous Mechanism of the Respiratory Movements. 38 pages. By E. H. Starling.

The Muscular and Nervous Mechanisms of the Digestive Tract. 34 pages. By E. H. Starling.

The Muscular Mechanisms of the Generative Apparatus. 6 pages. By E. H. Starling.

The Mechanical, Normal and Electrical Properties of Striped Muscle. 97 pages. By J. Burton Sanderson.

Nerve. 100 pages. By Francis Gotch.

Physiology and Electrical Organs. 40 pages. By Francis Gotch.

The Nerve Cell. 23 pages. By E. A. Schäfer.

The Sympathetic and Other Related Systems of Nerves. 80 pages. By J. N. Langley.

The Cerebral Cortex. 86 pages. By E. A. Schäfer.

The Spinal Cord. 100 pages. By C. S. Sherrington.

The Parts of the Brain below the Cerebral Cortex. 37 pages. By C. S. Sherrington.

Cutaneous Sensations. 81 pages. By C. S. Sherrington.

The Muscular Sense. 25 pages. By C. S. Sherrington.

Vision. 122 pages. By W. H. R. Rivers.

The Ear. 58 pages. By John Gray McKendrick and Albert A. Gray.

On Vocal Sounds. 30 pages. By John Gray McKendrick and Albert A. Gray.

The Sense of Taste. 22 pages. By I. B. Hayercraft.

There is in addition a most extensive index of subjects, covering 75 pages.

The Prevention of Valvular Disease of the Heart.

By RICHARD CATON, M.D., F.R.C.P. With 6 illustrations. London: C. T. Clay & Sons. 1900.

Dr. Caton, from a long experience in the Liverpool Royal Infirmary, has formed very positive views about the treatment and prevention of valvular deformity in rheumatic endocarditis. His little monograph is based upon a study of 86 cases. The author, like so many other physicians, has been discouraged by the enfeebling and shortening of so many valuable lives which occur from this disease, and particularly so since the crippling of the heart happens in so many cases early in life and the sufferer, instead of keeping step with his fellows is compelled to fall out of the ranks, losing hope, and even the power to earn his daily bread. Dr. Caton's book is suggestive not so much for the novelty of his views (for there is really little that is original in it) as for the force and insistence with which he presents them. His plan of treatment is by prolonged rest, after all the symptoms of acute articular disease have disappeared, counterirritation over the heart by blisters, and the exhibition of the iodids. In the acute articular stage he, of course, uses the salicylates freely. He claims that a beginning valvulitis, when recognized early, can be arrested and cured by this means, and says that the mistake too often made in practice is of regarding a slight endocarditis as beyond therapeutic help, and permitting the patient to leave his bed too soon. He enjoins absolute recumbency for several weeks. He is careful to state that he does not claim to cure well advanced cases of rheumatic valvulitis. His book is devoted rather to prophylaxis and the treatment of incipient cases, and is an excellent and suggestive work.

A Comparative Study of Digitalis and its Derivatives.

—Arnold and H. C. Wood, Jr. (*American Journal of the Medical Sciences*, August, 1900), as the result of a series of experiments draw the following conclusions: 1. Digitalin and digitoxin each represent the full circulatory powers of digitalis. 2. Digitalis, digitalin, and digitoxin stimulate the cardioinhibitory mechanism both centrally and peripherally. In larger doses they paralyze the intrinsic cardioinhibitory apparatus. 3. They all cause a rise of blood-pressure by stimulating the heart and constricting the bloodvessels. 4. Very large doses paralyze the heart-muscle of the mammal, the organ stopping in diastole. 5. Digitalin of Merck is a stable compound, 1 gram of it being equivalent to about 18 drams tincture of digitalis. 6. Digitoxin is not to be recommended for human medication on account of its irritant action, which makes it liable to upset the stomach when given by the mouth or to cause abscesses when given hypodermically, and on account of its insolubility, which renders it slowly absorbed and irregularly eliminated, having a marked tendency to cumulative action.

Laryngeal Tuberculosis.

—Cohn (*Journal of the American Medical Association*, November, 1900) divides laryngeal tuberculosis, as regards its therapeutics, into three stages. In the first stage, with the exception of a circumscribed infiltration, or ulceration, the larynx is healthy. In this stage, the only one in which a permanent cure can be hoped for, the treatment consists in curetment in case an infiltration be present; in cauterizing with lactic acid in case an ulcer be present. If the general condition, especially that of the lungs, be good these procedures are imperative and should be repeated at intervals of from 1 to 3 weeks until the diseased condition is completely removed. In the second stage the larynx presents extensive infiltrations or ulcerations. Here complete elimination of the morbid tissue can no longer be hoped for, but antiseptic treatment comes to the front, the author preferring antiseptic inhalations of carbolic or boric acid or lysol. If the epiglottis permit of an inspection of the interior of the larynx, the antiseptic swab can be used to advantage. By these methods secondary infection, and the terrible dyspnea and dysphagia of the last stage is prevented. Finally, if the case is first seen in the last pitiful stage, all that can be done is to treat it symptomatically, to administer a morphin powder before each meal, or, better still, to apply a 10 or 20% solution of cocaine to the pharynx. In impending suffocation, tracheotomy must of course be performed.

Correspondence.

PSEUDOMENSTRUATION.

By ALFRED H. SCOFIELD, M.D.,

of Coggon, Iowa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

A CASE of pseudomenstruation has just come to my notice. On November 5, Mrs. — was delivered of twins, male and female. Labor was extremely easy, and the infants were well formed and strong, weighing a trifle over 8 pounds each. About 7 days later the mother informed me that there was present in the female child a vaginal discharge, slightly bloody, lasting but a few hours. It had disappeared when I saw the child, but there is in my mind no doubt as to the nature of the discharge.

FOREIGN BODY IN THE AIR-PASSAGES.

By W. A. JOLLEY, M.D.,

of Rawlins, Wyoming.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE article on "Foreign Bodies in the Air-passages," in a recent number of THE PHILADELPHIA MEDICAL JOURNAL, recalls to mind a peculiar case which came to my notice.

A. L. M., aged 18, was chewing a stalk of timothy; when near the head he inhaled the stalk and head. He fell over and was supposed to be dead, but revived in a few minutes. He then had a severe bronchitis and spat blood. He thought that he had swallowed the head of timothy and could not account for the lung trouble which was supposed to be tuberculosis by several physicians who examined him. He came West, but did not gain health until one day after a severe spell of coughing he raised what he thought was a piece of lung, but on examining it closely he found the head of timothy which he had inhaled 2½ years previous. He began to improve at once, and now, 18 years after, is a strong healthy man with the exception of a bronchorrhea.

PERCENTAGE OF FAILURES.

By J. W. HOLLAND, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

A FEW days ago I saw a report of the number of graduates of Jefferson Medical College that failed in the July examination before the State Board. The paper bore on it the stamp of the Alumni Association of the University of Pennsylvania and contained a very laudatory notice of the University, making odious comparisons with other institutions. It stated that there were 38 graduates of Jefferson and 4 failures among them.

I have obtained from Dr. Hulshizer, who is a member of the Medical Council, an official list now in my possession of the average of each candidate before the Medical Council. According to that official statement there were 35 Jefferson men, graduates of the class of 1900, that applied, and three of them failed. The report emanating from the University Alumni probably counted in the same graduates from Jefferson College that have applied a number of times, one of whom

failed this year, as he did last. I protested last year against the practice of publishing these repeated failures of one man who graduated years ago as if they were failures of the class of this year, when our standard has risen with the standard of the Medical Council. As I make it out, we had 35 applications of class 1900 and 3 failures, and the total general average of our applicants of class 1900 was 81.94%.

TUBERCULOSIS AND RUSSIAN JEWS.

By MAURICE FISHERBERG, M.D.,

of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN a paper published in your valuable JOURNAL for December 1, 1900, entitled "Where the Danger Lies in Tuberculosis," by A. Dutcher, the writer made a few mis-statements which should not pass uncorrected. At first the author classifies as follows: "Our 190 (tuberculosis) patients divide themselves naturally (?) into blacks, whites, and Russians." Such a classification reminds me of the explorer who described a foreign country as containing a flora, a fauna, and elephants. Then the author proceeds to reveal "a most distressing state of affairs among the Russians, who are dangerous elements in our midst as breeders and spreaders of this disease" (tuberculosis).

The danger in tuberculosis consequently lies in the Russian elements. The author has discovered this fact while visiting tuberculous patients in Baltimore, "giving them a few simple instructions of the nature of the disease, the mode of its contagion, and methods of its prevention." By these means 20 Russians have been visited, and the observations among this large number of patients have convinced the author that the real danger for Baltimore, and the United States for that matter, lies in the Russians.

Miss Dutcher will surely be amazed to hear that the Russians (Jews) are not only not a dangerous element as breeders and spreaders of tuberculosis in Baltimore, but that the fact is that of all the races and nationalities living in the United States the Russian Jews are the least affected by tuberculosis, or any other fatal disease for that matter, except diabetes.

On consulting the Report on Vital Statistics of New York and Brooklyn of the eleventh census of the United States, we find that the death-rates from tuberculosis in New York during a period of six years, ending May 31, 1890, were for each 100,000 of population for each of the following nationalities: Colored, 744.21; mothers born in Ireland, 645.75; Bohemia, 499.13; Scotland, 384.12; Scandinavia, 357.00; Germany, 328.80; France, 324.98; England, and Wales, 205.14; Hungary, 155.05; Russia and Poland, 93.21.

On looking at these statistics, based on a Russian population in New York in 1890 of over 80,000, it does not look as if the Russians were "dangerous elements in our midst as breeders and spreaders of tuberculosis," the conclusion to which Miss Dutcher arrived on visiting 190 consumptives, 20 of which were Russians.

One more point: Under the name Russian I understand that Miss Dutcher means Russian Jews. It is a well known fact conceded by almost every authority on the subject that the proportion of Jews attacked by tuberculosis is very small in comparison with other nationalities. Dr. John S. Billings, who, by virtue of his having been an expert special agent for the census office of the eleventh census in the United

States, has made a special study of vital statistics in the United States, states plainly that the "members of the Jewish race possess a distinctly higher degree of immunity against the bacillus of tuberculosis and the micrococcus of pneumonia as compared with other races." (See Allbutt's System of Medicine, Vol. 1, p. 20.) And in almost every textbook on medicine and in every paper on tuberculosis where the question of the influence of race and nationality on the mortality from tuberculosis is discussed, it is almost invariably mentioned that the Jews are the least affected by this disease. A statement to the contrary, with special emphasis that the Russian Jews are breeders and spreaders of tuberculosis, could only be made by one whose conclusions are drawn from a study of the enormous number of 190 cases, 20 of which are Russian Jews.

Miss Dutcher makes a statement that house to-house visitation to teach tuberculous patients to destroy the sputum, to throw open the windows to admit the sunshine and fresh air, is productive of good results and adds:

"I feel that most of these individuals, unless they be Russians, are teachable."

This again is far from being a fact: Physicians who practise among this people will testify that the poorer working classes of the Russian Jews are as teachable as any other nationality of the same social status.

The fact is that they are not bad pupils, but that the individuals who undertake to do the teaching are not well prepared for the task, because they are not acquainted with the habit, social conditions, and language of the Russian Jews.

Any intelligent physician or trained nurse of Russian Jewish descent could do the work easily and satisfactorily.

PAIN IN THE BACK AND HEADACHE AS SYMPTOMS OF INTESTINAL DISEASE.

BY ALEXANDER R. BECKER, M.D.,

of Seattle, Washington.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I HAVE just read your capital editorial on Pain in the Back as a Symptom of Intestinal Disease (November 17th, p. 919), and beg to offer a few additional remarks, based upon my personal experiences and professional observations during the last forty years.

During McClellan's Peninsular Campaign of 1862, great numbers of our men were prostrated with the enteric fever, then and since called "Chickahominy fever," and their invariable and bitter complaint was: "Oh! doctor—my back, my back!" We were not strong on pathology in those days, and I do not know that any autopsies were made with a view to explaining that symptom, but I am perfectly sure that the enteritis extended to a severe colitis at the time, and has persisted in a chronic—sometimes only recurrent—form in very many cases, and I am suffering from it still, although only one of the original five strictures now remains, and I have had a number of patients among the veterans of that campaign who have suffered more or less as I have, and still complaint is made of the weary, wearing backache, which grows so much more severe with every exacerbation, or even with the delayed movement so frequent with a sluggish peristalsis.

I have also had quite a number of patients suffering from this latter condition—usually, but not always, middle-aged and stout—who have complained wearily or savagely of

backache, and in whom the location of the delayed fecal matter could be told by the region of the headache, the latter coming on in the right temple and side of the head as the offending matter was slowly passing up the ascending colon, passing to the forehead, and still more to the back of the head and neck as it traversed the transverse colon, and then to the left side of the head as it passed on downward—to be sometimes almost instantly relieved on defecation, but, at other times only intensified thereby, until, after an interval, a small, dark, partly watery and putrid discharge brought peace and comfort.

Backache, headache, colds—how vast a proportion of adult ills and pains are covered by those terms, and yet how little of really scientific or painstaking (no pun intended) thought is given them either by the investigator or writer, or practitioner, but all three arise largely from autointoxication—appreciating which, we can already give much relief, and more light will come.

A RARE ANOMALY; ATRESIA ORIS.

BY CHARLES D. LOCKWOOD, M.D.,

of Los Angeles, Cal.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I WISH to make a preliminary report of an extremely rare anomaly, which recently occurred in my obstetrical practice:

History of case: November 3, I was called to see Mrs. H. at 6.30 A. M. She thought herself in labor, and said she had a free discharge of water during the night from the vagina.

Menstrual history: Has had 4 children, one born prematurely. Labors were normal. Last menstrual period began March 15.

Examination: Fundus uteri midway between umbilicus and ensiform. Fetus freely movable; head not engaged; active fetal movements; heart-sounds and uterine bruit distinct.

Per vaginam: Cervix high up; external os patulous, internal os closed; rectum full of hard feces. There were no periodic uterine contractions. I concluded that the bag of waters had ruptured prematurely, but the woman was not in labor. This proved to be the fact.

November 12, 8 A. M.: Called again to see the woman. She had been in severe pain during the night. Since 3 A. M. pains had been cramp-like and abdominal, accompanied by free discharge of blood and water from the vagina. Abdominal palpation showed regular and painful uterine contractions. Fetal heart-tones distinct, 150 per minute.

Vaginal examination: Cervix well dilated, fetal head at vaginal outlet. Head presented, occiput anterior, closely enveloped in amniotic sac. Amnion stripped from fetal head after delivery, when child immediately became intensely cyanotic. Unable to find an explanation for the cyanosis, delivery of the body was hastened by traction. After a few heart-beats child died and cord was cut. It proved to be a monster, i. e., cyclopia or synophthalmia.

The only facial organ approximating perfect formation is a single eye situated in the median line at about the normal location for the root of the nose. The supraorbital ridge and upper lid are imperfectly developed. The lower lid is represented by a fold of skin lined with mucous membrane. There is a total absence of the nose and ears. At the lower angle of the face is a tag of skin resembling the upper lip, but there is complete *atresia oris*.

The branchial arches, which go to form the lower maxilla and upper respiratory organs, are represented by two or three pockets in the skin of the neck to the right of the median line.

The child otherwise is well nourished and perfectly developed. Weight, 6 pounds.

Careful inquiry failed to elicit any important hereditary influences bearing upon the etiology of the case.

The father is mentally weak as the result of sunstroke several years ago.

The mother rode a bicycle continuously the first three months of pregnancy, and in the early weeks of gestation fell from her wheel with considerable violence.

The amniotic sac formed a tight cap over the fetal head, and this may have had some bearing upon the maldevelopment as claimed by Geoffrey St. Hilaire, who has made a careful study of fetal monstrosities.

The specimen is in the museum of the Los Angeles Medical School. After suitable preparation, careful drawings will be made and the development of the brain and respiratory tract studied in sections.

I am unable to find any similar case figured. Ziegler pronounces the condition of atresia oris extremely rare.

APPARATUS FOR ADMINISTRATION OF CHLOROFORM.

By WILLIAM B. HIDDEN, M.D.,
of Boston, Mass.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

It was certainly a commendable idea to devote an issue of your always interesting JOURNAL to anesthesia. No one can read that number without concluding that the disadvantages attending present methods are numerous, and, however the writers may be groping after something better, none seem satisfied with results obtained. Anesthesia has never received the professional attention that it deserved. Custom has barred the road to progress by taking students, without any previous thought or training, to administer the anesthetic, and their success has been solely judged by the rapidity with which they prepared the patient for the operator. Hence the anesthetizer and surgeon have bestowed so little thought upon the subject, that the idea of the expansive effect of the patients' breath coming directly upon the anesthetic, has never entered their minds. Yet it is easily proved that all the discomfort, suffering and deaths incident thereto are clearly traceable, by natural law, to this one factor.

It is a provable fact that the expansive, evaporative pressure of ether and chloroform at a normal temperature just equals the atmospheric pressure, and every degree of heat added, correspondingly increases it, so that the breath of the patient produces an evaporative pressure of more than two atmospheres, and generates a coldness that will encase a glass container in ice in five minutes. It is this coldness taken into the lungs that has caused pneumonia to follow the use of ether. It is this rapid expansion from the contact of the breath that has asphyxiated the patient, given the anesthetic in unequal quantities, and but for the frequent removal of the cone to replenish the anesthetic, would have been very often attended with fatal results. These are facts, not theories.

It is a self-evident truth that true inhalation demands and should receive a normal amount of fresh air with each inspiration; this, by the usual methods of giving anesthetics, is made impossible by the laws of physics. As we cannot change the laws of Nature, we must change our methods to harmonize with them. So an instrument, simple in construction, has been devised, that automatically gives a nor-

mal amount of fresh air, impregnated with the anesthetic by a revolving current over it, insuring an equal quantity of the chloroform with each inspiration, and by the automatic action of valves, preventing the breath of the patient from contact with the anesthetic, and making every breath a fresh one, laden with the vaporized anesthetic. Experience with this instrument shows that what we called the sedative effects of chloroform are due to the want of oxygen and not to its supposed action upon the heart or nerve-centers; that the difference between vinous intoxication and that of anesthetics given by this method, is simply a matter of degree and no more dangerous. The person who readily yields to vinous intoxication, as readily yields to anesthetics and the reverse, though rarely can individual susceptibility be predetermined, nor can any instrument make the time uniform.

Assuming the correctness of the principle involved in this fresh-air method, which no one has ever disputed, the next important query must be, what anesthetic will bear the natural dilution of air and still secure complete anesthesia as uniformly and quickly as consistent with absolute safety?

Chloroform will do this, ether will not.

It has been truly said that statistics of the deaths from the use of chloroform and ether are not reliable. No better illustration of the fact need be given than that the deaths from pneumonia following the use of ether are never credited to ether, as they certainly should be; if they were the writer has good reason for asserting they would exceed the deaths from chloroform.

Nature's best gifts to man have been sources of danger until he learned how to use them in accord with her laws, and it is only in conformity with her as coworker that we reach our highest attainments; so in the use of chloroform, experience founded upon an utter disregard of the law of expansion by heat, is not a reliable or even tenable basis of judgment as to results, when Nature becomes a harmonious coworker with us, and its benign effects are engrafted upon natural sleep.

Three Microorganisms Other than Klebs-Löffler which Produce Membranous Angina. — Bassell (*Buffalo Medical Journal*, December, 1900) says the Bureau of Bacteriology in the city of Buffalo has observed that *Streptococcus pyogenes*, and the micrococcus of sputum septicemia, which belong to the bacteria, and *Oidium albicans*, which belongs to the group of fungi, are each capable of producing a pseudomembranous inflammation which macroscopically cannot be differentiated from that produced by the Klebs-Löffler bacillus. So far as observed in that city the *Oidium albicans* has never caused a fatal angina; but at least one death has been caused by each of the other germs named, in both of which cases the antitoxin of diphtheria was used without appreciable effect. Several deaths from the *Streptococcus pyogenes* have been reported in New York City, in which nothing but a bacteriologic examination could distinguish the infection from a true diphtheria. The author draws the following conclusions: 1. *Streptococcus pyogenes* and the micrococcus of sputum septicemia can produce membranous anginas, accompanied by physical disturbances sufficient to result in death. 2. *Oidium albicans* produces pseudomembranous exudates easily mistaken for the Klebs-Löffler inflammation. 3. The only positive means of determining a Klebs-Löffler infection is by microscopic methods. 4. From the sanitary standpoint, as regards quarantine, anginas due to *Streptococcus pyogenes*, micrococcus of sputum septicemia and *Oidium albicans* require little consideration. [A.B.C.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. George Fales Baker of Philadelphia was married, on December 31, to Miss Walker of Pittsburg.

Dr. A. W. Butt, a well-known physician of Paoli, Pa., died on December 31st after two weeks' illness.

Lunacy Laws.—A conference of delegates representing the different county medical societies of New Jersey was recently held in New Brunswick for the purpose of recommending amendments to the present lunacy laws of the State.

Diphtheria Epidemic Feared.—The School Board of Berwyn, Pa., has made application to the courts for a sanitary inspection, owing to the recent deaths from diphtheria in that township. The disease is said to have made its appearance at Ardmore and Malvern. An epidemic of diphtheria is feared at Berwyn. In the home of William Baylis, Jr., every member of the family, except the father, was taken ill. Florence, aged 7 years, died. The death of another child at Berwyn caused President James S. Lockwood, of the School Board, to call the members together to discuss enforcement of quarantine regulations. It was decided to ask the State Board of Health for instructions, and the result was the advice to petition for a sanitary agent. The State Board declined actively to interfere with the authorities of the township.

Vital Statistics of Philadelphia for the week ended December 29, 1900:

Total mortality	467	
	CASES.	DEATHS.
Inflammation of appendix 2, bladder 1, brain 9, bronchi 8, kidneys 16, heart 1, lungs 56, pericardium 1, peritoneum 5, pleura 2, stomach and bowels 13, spine 1, veins 1		116
Lungs—hemorrhage of 2, tuberculosis of 65		67
Heart—disease of 43, fatty degeneration of 3, neuralgia of 1		47
Debility 1, marasmus 11, inanition 15		27
Apoplexy 27, paralysis 11		38
Carcinoma of breast 2, bladder 1, face 1, liver 2, rectum 2, stomach 4, uterus 3		15
Diphtheria	100	14
Convulsions		13
Casualties		12
Cirrhosis of liver		4
Croup, membranous		7
Typhoid fever	88	9
Septicemia		1
Old age		17
Suicide—shooting		1
Scarlet fever	34	1
Cerebrospinal fever	1	1
Abscess of head 1, psoas abscess 1, alcoholism 3, asthma 2, Bright's disease 7, burns and scalds 4, cyanosis 3, diabetes 1, diarrhea 2, disease of liver 1, dropsy of brain 2, dropsy of heart 2, dysentery 2, epilepsy 2, erysipelas 1, hemorrhage of brain 1, hemorrhage of stomach 1, gallstones 1, hernia 1, homicide 1, indigestion 1, measles 1, obstruction of bowels 1, poisoning by carbolic acid 1, rheumatism 3, sarcoma of lungs 1, shock—surgical 1, softening of brain 4, strangulation 1, tumor of brain 2, ulceration of stomach 2, uremia 14, knife 1, influenza 1, consumption of bowels 1		77

New Buildings for Philadelphia Hospital.—City Councils have appropriated \$80,000 for the erection of new buildings for the Philadelphia Hospital, one of which will be a children's hospital, and the plans for the different structures are now being drafted, so that proposals can be advertised for and work on the various operations commenced as soon as possible. Very little money has been expended by the city in the way of improving or adding to this institution during the past 25 years, and the facilities for accommodating the unfortunate men, women, and children inmates have been very meager. Adults and children have been forced, owing to insufficient accommodations, to occupy the same wards. It is proposed to expend the bulk of the funds that have been appropriated in the erection of a mod-

ern scientific hospital for the cure of children's diseases, thus removing the little ones from the evil communications they are now and have been for some time past subjected to.

NEW YORK.

Dr. Martin J. Downey, of Buffalo, has been appointed assistant surgeon of the Erie railway.

Dr. Julius Ullman, of Buffalo, has been appointed local correspondent of the *Journal of the American Medical Association*.

Smallpox.—Four new cases of smallpox were reported to the Board of Health of New York City, on December 31. They are all residents of Brooklyn.

Dr. Chauncey Pelton Smith, of Buffalo, was elected vice-president of the Western New York Alumni Association of the University of Pennsylvania, during its foundation meeting, held at Buffalo, December 17, 1900.

The Brooklyn Society for Neurology.—At the annual meeting of the Brooklyn Society for Neurology, held December 27, 1900, Dr. W. H. Haynes was elected president, and Dr. B. Onif, secretary, for the ensuing year.

Buffalo General Hospital.—The staff, their assistants, and the clinical instructors have organized a clinical society of the Buffalo General Hospital, for the purpose of a closer *esprit de corps*. Dr. Irving M. Snow was elected chairman; Dr. E. L. Ruffner, secretary pro tem.

Study of the Bubonic Plague.—The Board of Health of the City of New York has decided to build a laboratory to be devoted to the study of the bubonic plague. The contract has been let for a building to cost about \$20,000, to be located on the grounds of the Willard Parker Hospital.

The German Hospital of Buffalo (N. Y.) will be opened to receive patients about January 10. It is a three-story building with basement, of substantial, fire-proof construction, equipped with the most modern facilities. It was formally opened with a bazaar which lasted two weeks, with great success.

New York University.—The death of Dr. Henry D. Noyes, professor of ophthalmology in the Medical School of the New York University, has left a vacancy which has been filled by the appointment of Dr. John E. Weekes, University of Michigan, '81. Dr. Weekes has been a lecturer in the medical school for the last two years, in the same department of which he has been made clinical professor.

Dr. R. V. K. Montfort, for 40 years superintendent of public schools of Newburgh, N. Y., died on December 29, aged 76 years. In September, 1862, he entered the Federal Army as assistant-surgeon in the New York Volunteer Infantry and was on every battlefield of the Army of the Potomac from Chancellorsville to the end of the war. He was promoted surgeon in March, 1865, and was mustered out in June of that year.

A New Accident Hospital for Buffalo, N. Y.—Plans have been filed and ground broken for a four-story building to be known as the Emergency Hospital. It is to be 60 by 142 feet, of steel construction, and to cost in the neighborhood of \$60,000. It will contain a dispensary, a diet kitchen, an operating amphitheater, and a roof to be used as a solanarium. When completed it will be one of the most perfectly equipped emergency hospitals in this country.

A bitter controversy is waging between Commissioner John W. Keller, of the New York Board of Charities, and a number of physicians of that city. Mr. Keller has accused the physicians on the medical board of improper administration, and one of them of taking big fees, and the physicians, in turn, say that Mr. Keller has managed affairs at Bellevue Hospital on a political basis. The trouble for the medical board began when, in his investigation of the charge that a patient had been murdered in the insane pavilion, Commissioner Keller discovered what he thought to be a need of reform in the general administration of the hospital. A letter to the medical board last week was so plain as to leave the board no alternative but a defense.

The Case of Dr. Kindred.—Justice Leventritt, in the Supreme Court of New York, granted an order to show cause, under which George C. Spann, the lawyer who claims \$25,000 damages from Dr. J. J. Kindred for alleged negligent treatment in a sanitarium, will have to show why the order for an inquest by a Sheriff's jury to assess damages should not be set aside. Dr. Kindred alleges that he was never served with the summons and complaint, and knows nothing about the case.

State Commission in Lunacy.—Governor Roosevelt has removed from office Dr. Peter M. Wise, of New York, president of the State Commission in Lunacy, after giving him an opportunity to make an explanation of certain statements made by him to the Governor on December 10 and 11, in relation to the alleged sale through him of stock in a copper mining company of New Mexico, in which Dr. Wise was pecuniarily interested, to employees of State hospitals for the insane under the control of the State Commissioner in Lunacy; and, secondly, in regard to his part in the construction of an artificial ice plant on the grounds of the Long Island State Hospital at Flatbush. This explanation the Governor considers unsatisfactory. Dr. Wise's term would have expired on December 31. The Governor states that he will not fill the vacancy, leaving that duty to Mr. Odell when he assumes office in January.

CHICAGO AND WESTERN STATES.

Professional Devotion.—Dr. B. C. Brett, of Green Bay, Wis., who is attending a case of smallpox in that city, has been shunned by his townsmen as though he were plague-stricken. Dr. Brett has sacrificed all of his private practice to care for his single patient.

St. Luke's Hospital of St. Louis to be Rebuilt.—The directors of St. Luke's Hospital of St. Louis have raised within the past few months more than \$100,000 by voluntary subscription, for the purpose of removing the hospital from its present location and erecting a modern building.

State Sanitarium for Consumptives.—The State Board of Health of Illinois, in its forthcoming biennial report, will recommend the building of a State sanitarium for consumptives. It will also join with the State Board of Charities in favoring a provision for the special care of epileptics.

Plague in San Francisco.—Surgeon Kinyoun reports to the Marine-Hospital Service 6 more fatal cases of plague. Dr. Kinyoun believes that the infected area is increasing in size, there being now only three blocks in the Chinese quarter proper, in which there has been no case of plague since March last.

Physician Killed.—Dr. Hawkins, formerly of Knox, Mo., is dead at Ralston, O. T., the result of a cowboy of Moody's ranch knocking him down and dancing on his stomach. The doctor was over 60 years of age, and recently saved the life of his assistant, over the settlement for which services the fatal dispute arose.

Smallpox in Lumber Camps.—From the lumber camps of Michigan come reports that smallpox is epidemic there. Similar reports come from Poplar Bluff, Mo., and at Kansas City extraordinary sessions of the board of health were held to cope with the disease. A number of new cases have developed at Schenectady, N. Y.

San Francisco's Quarantine Station.—Vexatious and expensive detentions at the San Francisco quarantine station of coaling vessels from Nanaimo will hereafter be avoided by the action lately of Surgeon-General Wyman, who has arranged for giving vessels a clean bill of health at the port of sailing. The California Congressional delegation brought the matter to the attention of the Surgeon-General with the above result.

Physicians' License Law.—A case to test the Wisconsin physicians' license law of 1897 has been begun by Dr. W. M. Caswell, of Hillsboro, in that State, who has obtained a writ of mandamus to compel the State Board of medical

examiners to issue him a license as a doctor. The Board, he alleges, refused him a license last August. Dr. Caswell alleges that he has practised medicine in Wisconsin for 12 years. The case will be heard January 14, before Judge Siebecker, at Madison.

Diploma Mill Exposed.—James and Thomas Armstrong, principal officers of the Metropolitan or Independent Medical College of Chicago, were convicted recently in the United States District Court on three charges of having used the mails to defraud, in connection with one of the most notorious "diploma mills" in the country. The jury decided they were guilty under a statute which permits an extreme penalty of 18 months in jail and a fine of \$1,500 each. Sentence was deferred.

Contagious Disease Hospital.—A despatch from Lansing, Mich., under date of December 29, says: Attorney-General Oren has in an opinion declared that townships must erect contagious disease hospitals. Attorney Oren says that it is the intention of the Legislature that each township should establish its own hospital for communicable diseases. Secretary Baker, of the State Board of Health, will soon advise the township officers of this provision in the law, and recommend its immediate enforcement.

Consumptives' Home.—The next Legislature in Iowa will most probably be asked to establish an institution in that State for the isolation and treatment of those afflicted with tuberculosis. The Iowa State Board of Health has just issued 10,000 circulars to be distributed all over the State in an endeavor to arouse public sentiment to the necessity of this enterprise. It is stated that 9 persons die daily in Iowa from consumption. Dr. Coniff, a member of the State board, says that the board is determined to educate the people up to the danger of permitting consumptives to scatter the deadly germ broadcast.

Kansas Enacts New Medical Laws.—The Kansas State Board of Health has prepared a number of bills for introduction during the winter session of the legislature. One bill provides for the establishment of a State Board of Medical Registration and Examination, consisting of seven members. Their duties will be to issue certificates or licenses to persons who desire to practise medicine. They shall be required to pass an examination touching upon their qualifications. The law, however, will not apply to persons who have diplomas from reputable medical colleges or who have practised medicine in the State for 20 years or more. To these, certificates will be issued without examination. The law does not recognize persons who practise christian science, faith cures, spiritualism, etc., but licenses osteopaths who have taken a 4 years' course of instruction, and who do not use drugs or perform operations in their practice. Provision is made for the law to take effect in January, 1902, and any person who has not complied with its provisions by that time and attempts to practise medicine without a license will be liable to a fine of from \$50 to \$200.

A Good Year in Drugs.—An increase in the drug business for the year just closed of 10% was recorded. The trade had its sensational features, and in some respects was materially different from previous years. The war in China produced material advances in all Chinese drugs, but part of them were lost. In quinin there was an advance from 32 to 39 cents, but large importations of bark produced a reaction to the low point, and the close was heavy. Castor oil jumped up 12 cents and camphor 16 cents. The latter was due to a large consumption and a reduction in supplies. The increased demand for bismuth for army use caused an advance of nearly 50 cents. The most sensational change was in cocaine, due to various influences. Early in the year it sold from \$6.20 down to \$3.50, but advanced to \$6.75. The enlarged consumption of carbolic acid in the African war reduced European supplies, and prices advanced 50%. The year was not without material declines, among the most noticeable being a drop of 50 cents in salol. The drug sundries had a large sale, but they are handled more extensively now by dry goods houses and department stores than by wholesalers of drugs. The aggregate business of the year was \$10,000,000.

SOUTHERN STATES.

Attorney Apologizes.—A full written retraction, with ample apologies, was made by Attorney A. J. Speckert, who recently filed a \$45,000 damage suit for Ida Mellinger against Dr. William Cheatham, a prominent specialist of Louisville, affirming that Dr. Cheatham had imposed upon the girl while treating her professionally.

Dr. Hartigan Sues University.—Dr. Hartigan, head of the medical department of the West Virginia University, has entered at Morgantown, West Virginia, suit for \$25,000 damages against President J. H. Raymond, of the university. At the meeting of the Board of Regents Dr. Hartigan was deposed from his position on the recommendation of President Raymond.

Influenza Epidemic.—An epidemic of la grippe has possession of Fort Worth, Texas, and the cases are numbered by the thousands. The symptoms this year are high fever, acute pain, particularly affecting the upper and back part of the head. The weather had been exceedingly mild and the recoveries, as a rule, are rapid. A few cases of meningitis have followed the attack of la grippe, one fatal.

The Virginia State Veterinary Association held its annual meeting in Richmond, Va., December 28. Dr. E. R. Niles, of Blacksburg, was elected president, Dr. H. S. Drake, of Leesburg, first vice-president, and Dr. H. Bannister, of Roanoke, secretary and treasurer. While the large majority of the members are of course veterinarians, still physicians are eligible to membership and some do contribute papers on subjects of common interest to both professions. The next meeting will be held in Norfolk, Va.

MISCELLANY.

Obituary.—DR. GEORGE G. TARBELL, of Boston, on December 29.—DR. ERASTUS E. MARCY, at New York City, on December 29.—DR. LOUIS SCHNEIDER, aged 56, of Williamsport, Pa., on December 29.

New X-ray Apparatus.—Cowe describes an apparatus by means of which the interior of the thorax can be photographed during respiration. Pictures are said to have been obtained, illustrating the intrathoracic contents at various stages of respiration.

Pneumonia in Alaska.—A Dawson, Alaska, dispatch, of December 18, states that there had been 5 deaths in as many days from pneumonia. The disease was spreading rapidly. Typhoid fever also had been epidemic, but subsided when cold weather set in.

Unusual Hyperpyrexia.—Dr. F. B. Jewett, of Howard, R. I., in *Providence Medical Journal*, reports a case of chronic mania, in which the temperature would go below 96° for several times a number of days in succession, and several times reached 94.6° to 94.8°.

Resignation of Dr. McGee.—The following correspondence relative to the resignation of Dr. Anita Newcomb McGee is of interest:

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL.—The Army organization bill contains a section putting the Army Nurse Corps into the regular military establishment, which section was written by me at the request of the Department. As it provides for the creation of the office of superintendent of the Army Nurse Corps, the almost certainty of its passage has seemed to offer a good opportunity for my leaving. Under present conditions there is no such position as superintendent of the nurse corps and therefore no vacancy to fill until the bill goes through. In order, however, to be able to leave without waiting for that, a temporary arrangement has been made by which one of the chief nurses (Mrs. D. H. Kinney) is to carry on the work, and if she chooses to accept it she will of course be offered the appointment of superintendent.

Very sincerely,

ANITA NEWCOMB MCGEE.

COPY.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, November 20, 1900.

To the Surgeon-General U. S. Army, Washington, D. C.

SIR:—The experimental and organizing stages of the Army Nurse Corps being now passed, I have the honor to tender my resignation as in charge of that body, and to ask that my work be carried on by another.

I also tender my resignation as Acting Assistant Surgeon, U. S. Army.

I cannot take leave of your office, with which I have been connected for over 24 years, without expressing in some small degree my pleasure in having been so closely associated with your administration, and having been able to render some little assistance in your very arduous and responsible duties. I wish also to thank you, and through you the officers and clerks in this office, for many courtesies received, the memory of which will remain always with me.

Very respectfully,
(Signed) ANITA NEWCOMB MCGEE,
Acting Assistant Surgeon, U. S. Army,
Exchange Army Nurse Corps.

COPY.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,

WASHINGTON, November 21, 1900.

Dr. Anita Newcomb McGee, Acting Assistant Surgeon, U. S. Army, in charge Army Nurse Corps, Surgeon-General's Office, Washington, D. C.

MADAM:—I have the honor to acknowledge the receipt of your letter dated November 20, 1900, in which you tender your resignation as an Acting Assistant Surgeon, U. S. Army, in charge of the Army Nurse Corps.

In accepting your resignation I desire to express to you my high appreciation of the valuable services you have rendered during the past 24 years in selecting trained female nurses for duty at our field and general hospitals wherever their assistance has been necessary, and in organizing the "Army Nurse Corps" upon a satisfactory basis. You have shown excellent judgment and executive ability, and have labored zealously both in the interests of the nurses and of the Government.

Your contract will be annulled December 31, 1900.

Very respectfully,
(Signed) GEO. M. STERNBERG,
Surgeon-General, U. S. Army

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended December 28, 1900:

Changes in the Medical Corps of the U. S. Navy, for the week ended December 29, 1900.

LEDBETTER, R. E., assistant surgeon, detached from the "Monongahela," and ordered to the "Constellation."
BUEB, C. R., assistant surgeon, orders of December 19 revoked, and to resume duties on the "Monongahela."
BRADLEY, G. P., medical director, commissioned medical director from May 31, 1900.
FITZSIMONS, P., medical director, commissioned medical director from November 19, 1900.
JONES, W. H., medical inspector, retired, died at Bethlehem, Pa., December 13, 1900.
BARBER, G. H., surgeon, commissioned surgeon from June 7, 1900.
RODMAN, S. S., assistant surgeon, appointed from December 14, 1900.
BRISTER, J. M., assistant surgeon, appointed from December 14, 1900.

Changes in the U. S. Marine-Hospital Service, for the week ended December 27, 1900:

McINTOSH, W. P., surgeon, to proceed to Columbus, Ga., for special temporary duty. December 23.
DECKER, C. E., assistant surgeon, granted leave of absence for 14 days on account of sickness. December 24.
BAHRENBURG, L. P. H., assistant surgeon, relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Manila, P. I., and report to the chief quarantine officer for duty. December 27.
DUFFY, FRANCIS, acting assistant surgeon, granted leave of absence for 6 days from December 29. December 24.
LINLEY, W. J., acting assistant surgeon, granted leave of absence for 30 days. December 22.

Foreign News and Notes.

GREAT BRITAIN.

Dr. Alexander Deas Davidson, of Swansea, a well-known ophthalmologist, died on December 7.

New Departments in the Royal Hospital, Belfast.—The Board of Management have just given their consent to a suggestion from the medical staff to establish a new special department for dermatology (the work to be done by one of the present staff), and to appoint 2 anesthetists, whose duty it will be to administer ether, chloroform, etc. It is felt that the time has come to specialize in the administration of anesthetics and also to teach students in such important medical duties.

Death of Dr. James Michell Winn.—Dr. James Michell Winn died at his residence in Hampstead on December 8, in his 92d year. He was, it is stated, the oldest doctor of Glasgow, and also the fourth in the list of the Members of the Royal College of Physicians; he was not the oldest in point of age, there being a senior to him by 6 months among the Fellows of the College. Dr. Winn was born in the parish of Budock, in Cornwall, on December 25, 1808. When about 5 years of age he went to reside with his parents at Lisbon, and was a resident in the Peninsula when the battle of Vittoria was fought in 1813. He commenced his medical studies at St. George's Hospital under Sir Benjamin Brodie and Dr. Chambers. He heard Mr. Abernethy deliver a lecture on one occasion, and was struck with the clear and practical style of the lecturer. On leaving St. George's Hospital he went in 1832 to the University of Glasgow to study for the M.D. degree. At that time the cholera had made its first appearance in England, and the average daily deaths at Glasgow amounted to upwards of 100. This gave him a good opportunity of studying the nature and treatment of that complaint at the Cholera Hospital. On returning to England he was appointed honorary physician to the Royal Cornwall Infirmary, a position he retained for 14 years. In 1852 he settled in London, where he made psychology his chief study, and contributed numerous articles on that subject to the *Journal of Psychological Medicine*. He had written previous to this, in 1848, a treatise on "General Paralysis of the Insane." In a work on the "Nature and Treatment of Hereditary Disease," published in 1869, he propounded a theory that all hereditary disease was interchangeable—in other words, mutually convertible. Dr. Winn was buried at Kensal Green on December 12.

CONTINENTAL EUROPE.

Gold Medal for Dr. Potain.—Dr. Potain will have reached the age limit prescribed by French law for service in the universities at the end of the year 1900. His colleagues have decided to present him with a gold medal on the occasion of his retirement from academic life, and a fund is now collecting for this purpose.

New Russian Medical School.—The first semester of the newly established medical school in Odessa opened on September 1, with a lecture on physics by Professor Schwedoff. Dr. Podwyssotsky, professor of pathology, has been appointed dean, and Dr. Batoujeff, professor of anatomy, is secretary of the new faculty of medicine of the University of Odessa.

First Woman Pharmacist in Russia.—Mme. Lesnievskaja, who has received the degree of Master of Pharmacy, has also secured the necessary authorization from the government to open a pharmacy in Moscow. She is the first woman in Russia to be accorded this privilege. In connection with her establishment there will be a chemical laboratory and a school for women pharmacists.

Compound Fractures.—Nicholas Senn (*The Chicago Medical Recorder*, October, 1900) says the adoption of the classification "open" and "closed" fractures, which has been proposed recently, would do away with much of the confusion which has arisen in regard to simple, compound, and complicated fractures. The special immediate danger in compound fracture is the exposure of the medullary tissue to infection. It is particularly susceptible, and antiseptics even in the most careful hands will not always prevent osteomyelitis. He quotes statistics recorded previous to the antiseptic era, which show a mortality of almost 50% in compound fracture cases. This he contrasts with a mortality of but little more than 5% under the present antiseptic treatment. The author says while the latter has done so much in the way of saving life, it has perhaps done more in the preventing of mutilating operations, primary and secondary amputations, and resections, and in shortening the healing process, and in improving and increasing the functional results. Under strict antiseptic precautions, timely employed, the majority of compound fractures heal in the same manner as simple fractures, in the same length of time, and with no more suffering and equally satisfactory functional results. Formerly the surgeons, who had become painfully aware of the great dangers arising from inflammation, aimed to prevent and combat it by the employment of energetic antiphlogistics, application of cold, restricted diet, venesection, sedatives, emetics, and cathartics; the modern surgeons score such marvelous results by excluding or rendering harmless the direct cause of infection, and by husbanding the strength and recuperative energies of the patient. Subcutaneous fractures suppurate only in exceptional cases, even in the event that the bone is extensively splintered, and the soft tissues are seriously injured. Lister, based on Pasteur's researches, showed that it was not the atmospheric air, as was formerly believed, but the micro-organisms suspended in it that produced the fermentation and putrefactive processes in the primary wound secretions. The modern treatment of a compound fracture enjoins a heavy responsibility on the attending surgeon. Under ordinary circumstances, and in recent cases, he is expected to protect the wound against infection, and the patient from its serious, immediate, or late consequences. After eliminating the cases requiring primary amputation, two leading indications present themselves: (1) Healing of the wound; (2) repair of the fracture. Upon the results of the first examination must depend the propriety of a primary amputation. Heretofore surgeons have placed too much reliance on the extent of comminution of the fractured bone in deciding this important question:—Is amputation necessary? Experience has shown that the condition of the soft tissues is more important in determining the advisability of adopting a conservative plan of treatment. The condition of the vessels, nerves, muscles, skin, and neighboring joints should influence the surgeon in arriving at final conclusions as to what course he should pursue.

1.—Taylor reports the case of a woman, aged 39 years, who was suffering from pain and swelling in the abdomen. The patient came under his care as a case of ascites, and the point to be determined was the origin of the peritoneal effusion. The choice seemed to lie between tuberculous peritonitis and cirrhosis of the liver. When, after a few days, the dulness increased in an upward direction, it became highly probable that there was a liquid effusion into the pleura as well as into the peritoneum. This frequent association of the serous cavities in a common lesion is a fact which has long attracted attention not only in the case of combined tuberculous peritonitis and pleurisy, but also in the case of some more acute diseases, such as acute rheumatism and pyemia. Italian physicians have given the names *polyserositis* and *polyorrormentitis* to this multiple inflammation of the serous cavities. The author considers the latter term to be the more desirable. We must guard ourselves, however, from regarding this combination of lesions as a separate disease and from thinking that we have reached the bottom of a given case when we have given it this imposing name. It obviously only represents a common grouping of pathologic conditions of sufficient frequency to require attention, and sufficiently constant in its pathologic or etiologic antecedents to make its study fruitful. Polyorrormentitis may be acute, subacute, or chronic, and it may be due to the action of the pneumococcus, the streptococcus, the staphylococcus, the rheumatic poison, or the tubercle bacillus. It is more frequent in males than females, and the majority of the cases occur between the ages of 16 and 30 years. It is usual for one serous cavity to be invaded before the others. In the majority of cases the peritoneum is first attacked and the inflammation subsequently invades the other membranes. This invasion may occur according to the following 3 types: (1) The peritoneum is first attacked, then the pleura; (2) the pleura is first the seat of disease, then the peritoneum; (3) pericarditis follows a pleurisy. Some of those who have written upon the subject believe that subacute and chronic polyorrormentitis are nearly always tuberculous. The prognosis of polyorrormentitis in general must depend very much on the cause. The treatment of the condition must be conducted on the lines of the treatment of the separate tuberculous lesions concerned. The tuberculous nature of the lesion in the patient reported in the paper was demonstrated by a laparotomy, from which, however, no benefit was derived. [J.M.S.]

2.—Will be treated editorially.

3.—From 1885 to 1895 the applications for insurance in a large company numbered 5,115 and the risks declined or postponed were 409, or 8.11%. The causes that determined the rejected applications are: Family history of phthisis, 84; rheumatism in applicant, 31; lung diseases, 57; heart diseases, 50; genitourinary diseases, 81; diseases of the nervous system, 25; other causes, 90. Of these 409 rejected cases

Macphail has ascertained definitely that 204 are living and 31 are dead. Basing a calculation on the normal death-rate of persons of suitable age we should expect to have 25 deaths out of the 235 subjects; while, as a matter of fact, the deaths number 31. There is no factor in life insurance of more importance than a family history marked by tuberculosis. Of late years, however, it has been proved that a bad family history may be largely neutralized by a good personal record, the chief indication being the weight of the occupant. Dr. E. J. Marsh has made this very clear and is led to the following striking conclusions: 1. That the history of consumption in any member of the immediate family increases the probability of its appearance in an applicant. 2. That consumption in a brother or sister is at least of equal importance as when it has occurred in a parent. 3. That persons who are under the standard or average of weight are much more liable to consumption than those above this standard. That the peculiarity of constitution that is indicated by the inability to take and assimilate a proper amount of nutriment indicates a susceptibility to phthisis, or at least is a reasonable suspicion of such predisposition. 4. That persons who exhibit a robust or well-developed body have little susceptibility to consumption. 5. That the personal condition of weight and robustness has far more value than the family history in diminishing the liability to consumption. 6. That the evidence presented by a well-developed body may outweigh the suspicion attached to an unfavorable family record. 7. That these influences of family history and personal weight are of the same grade for every age, and their importance is not lessened by the fact that the individual has reached middle life. In relation to abnormalities of pulse, the important thing for life insurance is to establish that the unusual condition is peculiar to the individual, that it has persisted for many years, that it is not associated with any objective symptoms or with any impairment of health. Fifty cases out of the 409, or 12%, were rejected for causes connected with the heart, and the author has been able to discover only 5 deaths from heart disease. The matter of albuminuria must be viewed from the standpoint of the medical examiner as well as that of the director. To the director the term albuminous urine is one of sinister significance. On the other hand, injustice is wrought to many an individual from this cause and this is the side that appeals to the examiner. It is not a question whether or not a substance supposed to be albumin is present; it is a question whether or not the applicant is in good health. With all these conflicting elements the medical examiner must feel constrained to lay aside his favorable opinion of an individual case and classify it the black-list of albuminuria, no matter how favorably he is convinced that the after-history will be favorable. Many risks are refused on account of personal habits, especially in relation to the taking of alcohol. There is a wide difference of view by examiners on this point and that view is affected by the habits of the examiner himself. All are pretty well agreed, however, that alcohol in reasonable amounts and at proper times is not only harmless but actually productive of good. Indeed the case of a total abstainer should be searched into as diligently as the case of the habitual drinker, since abstinence may be due to a knowledge of hereditary taint, to personal intemperance in early life, or to some physical condition which does not go with robust health and long life. But there is a class of risks which all companies agree to consider bad. This is the class of liquor dealers and manufacturers that are brought into daily and intimate connection with alcohol. Many cases are rejected on account of pregnancy. This is to prevent women from insuring against that particular contingency, and rules are made accordingly. If a woman insures her life under the usual conditions the company lays no restrictions upon her childbearing, but they will not accept her within 2 years of her marriage nor until she has borne her first child, or until it is pretty clear that she will never have any. [J.M.S.]

4.—Clarke reports a case of varicose aneurysm of the aorta communicating with the pulmonary artery. The opening was about the size of a sixpence, while the thin, walled sac was only the size of a bantam's egg. The murmurs observed during life were low pitched, roaring and varying in intensity, as it were a background to a loud systolic and diastolic sound; these were loudest at the sternal end of the third intercostal space; no tracheal tugging or laryngeal paralysis was observed. [W.S.N.]

5.—Macilwaine defines **disease** as the sum total of the consequences resulting in a patient from the interference with his physiologic state by a disease cause. According to this definition diseases are divided according to their etiology into those due to intrinsic causes; those due to extrinsic causes; and those due to causes of undetermined origin. 1. Diseases due to intrinsic causes may be due (a) to wear and tear, such as atheroma; (b) to incomplete development, such as idiocy; (c) to failure of function, such as gout; and (d) to unphysiologic stress, such as writers' cramp. 2. Diseases due to extrinsic causes may be due (a) to parasites, such as tuberculosis; (b) to nonparasitic matters introduced into the economy, such as alcoholism; and (c) to deleterious physical interference, such as wounds. 3. Diseases due to undetermined causes may be due (a) to tissue overgrowth, such as carcinoma, and (b) to toxemias of unknown origin, such as cirrhosis of the kidney. [J.M.S.]

6.—White believes that if a disease is due to a specific causal agent it is not characterized by specific anatomical or functional lesions. If a disease is characterized by specific lesions we must not expect to find a specific causal agent. From this it follows that from the characters, histologic or macroscopic, of the lesions we cannot positively affirm that the disease is due to a specific causal agent. The only means by which we can affirm this is to find and isolate the causal agent itself. Variations in the characters of the lesions in diseases due to specific causal agents depend not on the nature of the agent, but on the locality to which it is applied and on its relative virulence. [J.M.S.]

7.—Williamson reports the case of a man, aged 21 years, a clerk, who was suffering from a peculiar persistent quivering of the muscles of the limbs, the trunk and the face. During the infancy of the patient, his left leg had become suddenly paralyzed and had remained useless. At the age of 16 years the paralyzed limb had been seriously injured and amputation had been necessary. The quivering of the muscles of the right leg began 2 years before the author saw the patient and spread gradually. The most striking symptom was the persistent, rapid quivering of the muscles of the right leg, the arm, the trunk, the face, and the tongue. Sometimes one small bundle of muscle fibers contracted rapidly, giving the appearance of fibrillary contraction; sometimes several bundles of muscle fibers contracted; and at other times the whole muscle contracted. The symptom was best seen in the leg, affecting the muscles of the calf and the thigh. The patient could perform all the movements of the arms and the legs and there was no localized wasting or paresis of the muscles. There was no rigidity of the limbs. The knee-jerk was a little increased; but there was no ankle clonus. The condition was diagnosed **myokymia**. [J.M.S.]

8.—The mortality in the epidemic of **cholera** in Kashmir, in 1900, was about 56%. Neve believes that prophylactic treatment with sulphuric acid is of value in averting the disease. The immense importance of early treatment with some preparation of opium cannot, in the author's opinion, be too strongly insisted upon; 70% of those treated by him in that way recovered. [J.M.S.]

9.—Welsford reports the case of a man who was suffering from a high degree of malarial cachexia. He had had frequent slight attacks of blackwater fever during the 3 years previous to the time that he was seen by the author. On admission to hospital the patient objected to taking quinin, alleging that a single dose invariably made his urine black; but he eventually consented to take 2 10-grain doses, the last of which was administered at 2 o'clock in the afternoon. At 6 o'clock the patient had a chill and his temperature rose to 105° with vomiting and pain and at 7 o'clock he passed 10 ounces of black urine. During the night he improved, the next morning his urine was clear although it still contained a little albumin. After the patient's temperature had remained normal for 7 days he was put to bed and on the third day 2 10-grain doses of quinin were given him with the same result. A more doubtful case of **quinin hemoglobinuria** occurred in a man who was admitted with a somewhat severe attack of blackwater fever which was treated without quinin with good result. Three weeks later the patient's temperature rose to 100° and 10 grains of quinin were ordered 3 times a day. Two days later his temperature rose suddenly to 105° and his urine became black and continued so for 2 days. Since in this case the symptoms were well marked, the attack may have been a relapse. [J.M.S.]

10.—Mackintosh reports the case of a woman, aged 53 years, who swallowed a large packet of **zinc sulfate**. She was suffering, when seen by the author, from severe pain in the stomach and bowels, pallor, cold extremities, irregular pulse, cold sweats and purging; but she had vomited only about a teaspoonful. The patient died in collapse about 20 hours after taking the **poison**. At the necropsy, the mucous membranes of the stomach and the large intestine were found to present patches of intense inflammation. The inflammation in the small intestine was intense and diffuse. [J.M.S.]

11.—Todd White suggests the term **metabolic fever** for a form of febrile affection that is common in children during the summer months and that is generally called a bilious attack. It is characterized by severe frontal headache, profuse perspiration, vomiting, constipation, or diarrhea, loss of appetite, and a temperature of about 101 or 102°. The author has been able to show that in every case that has come under his notice the patient has taken some unusual exercise during the days immediately preceding the attack. [J.M.S.]

12.—Harman describes a rather uncommon case where the necropsy showed that the right half of the **spinal cord** near the lumbar enlargement had been destroyed by **angiomatous growth**, and death evidently was produced by pressure from a hemorrhage. About 2 years before the patient died he began to show signs of progressive paralysis of the right leg, and at times had severe attacks of pain, while on several occasions spasms of the muscles of the leg and back; the one that caused his death was of longer duration, as well as more intense, and their cause was presumed to be due to **recurring hemorrhages**. [W.S.N.]

Medical Record.

December 29, 1900. [Vol. 58, No. 26.]

1. Some Remarks on Medicine in 1800. GEORGE K. WELCH.
2. A Case of Gonorrheal Endocarditis with Congenital Malformation of Mitral Valves. G. W. McCASKEY.
3. The Operative Treatment of Varicose Veins of the Lower Extremities. W. C. BORDEN.
4. Two Unusual Cases of Aphasia, with Special Reference to the So-called Naming Center. GRAEME M. HAMMOND.

3.—Borden does not believe in the palliative treatment of **varicose veins in the lower extremity** as it only too often causes extension of the diseased condition until some more serious complication follows. This may be obviated by **early operation**, when the disease is localized, and then at that time it can be permanently cured. He favors most the complete excision of the diseased vein, but when for some reason this is contraindicated, he finds that multiple ligation or excision of part of the vein yields the best results under the circumstances, and in a few cases where the above operation cannot be performed, high ligation of the saphenous may be tried, but it rarely proves as satisfactory as the more radical operation. [W.S.N.]

4.—Hammond records a case in which there was an injury of the cortex at the junction of the middle and posterior thirds of the superior temporal gyrus, and a second case in which there was an area of softening in the middle third of the second temporal gyrus. In both cases there was entire word-deafness, and in the second word-blindness. He believes that a lesion in any part of the speech-area may so disorder the mechanism of the associated speech-centers that any or all forms of aphasia may result and that there is as yet no real evidence that a single naming center exists and some evidence against such a view, and it is at least not very improbable that there is no such center. [D.L.E.]

Medical News.

December 29, 1900. [Vol. lxxvii, No. 26.]

1. The Nitrite Treatment in Syphilis. WILLIAM BROWNING.
2. The Failure of the Consensus Judgment with Reference to Tuberculosis. CHARLES DENISON.
3. The Value of the Schumburg Method of Purification of Water for Military Purposes. JOHN H. HUDDLESTON.

4. A Theory of the Physiology of Spinal Anesthesia. H. H. STONER.

1.—The author's reason for employing the nitrites in syphilis is the widespread tendency of syphilis to cause **arterial interference**. The results of this interference are a narrowing of the lumen. He employs the medicament as a **vasodilator**, thereby increasing the means of transportation for the remedy. The author calls attention to the title and emphasizes that it is intentionally made, Use *in* syphilis and not *for* syphilis. He considers hypodermic administration as quite unsuited, as it makes the action of the nitrite more temporary. A continuous action is necessary. One or two grains of the sodium salt are usually sufficient, at least for earlier doses. All of these agents are explosive if improperly handled. [M.R.D.]

2.—Denison opposes the **consensus judgment** relative to the home management and local hospital treatment of tuberculosis, and for the following reasons: (1) There is a decided advantage in **climatic change** over the home or the local sanitarium treatment, and (2) the **germ theory** of tuberculosis is not the sole cause of the disease, and so is not a sufficient foundation for either its educational or legislative control. [M.R.D.]

3.—A number of experiments with **bromin solution** as a disinfectant for water were made by the author. Cultures of **typhoid bacillus** were obtained from 3 sources, one from laboratory, one isolated from well-water, and one from the feces of a typhoid patient. Croton water was obtained from tap in laboratory from Hudson river at Albany, and from a pool that had been standing some weeks. It was inferred that for ordinary drinking water, the minimum amount of bromin solution, as proposed by Schumburg, was sufficient to disinfect typhoid and coli, while the ordinary air bacteria may be much more resistant. It was shown that, if sufficient bromin be employed, it is possible to even make stagnant water, under experiment, drinkable. Schumburg has devised a military pouch adapted for preparing a day's water-supply for a regiment of 1200 men. [M.R.D.]

4.—Stoner considers the term "medullary narcosis" as misleading, as it conveys the impression that the injection is made into the substance of the cord. The cell bodies are situated outside of the canal, therefore the poison does not gain access by direct infiltration. The most plausible theory is supposed to be the one, that the solution, thrown into the cavity occupied by the axones, is absorbed by the latter, and transferred by way of the vascular supply back to the cell. The motor neurons escape the paralyzing effect of the solution. Stimuli over the sensory tract are prevented from reaching their destination owing to paralysis and withdrawal of the arborizing extremity of the peripheral sensory neuron from contact with its associated one, but in the case of the peripheral motor neuron no such ending takes place. The reflexes are inhibited in the anesthetic area. A portion of the stimulus may pass up the ascending axone of the sensory neuron, and upon reaching the brain give rise to sensation, the other portion taking the reflex route, over the descending branch. It is self-evident that the solution paralyzes the arborizing processes of the collateral of the descending branch, as well as that of the ascending one, and the solution is, therefore, removed from functional relation to the peripheral motor neuron. [M.R.D.]

December 27, 1900. [Vol. cxliii, No. 26]

1. Operative Treatment of Goiter. J. COLLINS WARREN.
2. Statistics of Operative Treatment of Thyroid Tumors. LINCOLN DAVIS.
3. Neoplasms of the Thyroid Gland. CHAS. G. CUMSTON.
4. The Practical Use of Vital Statistics. FREDERICK L. HOFFMANN.

1.—Warren operates in the young, where a rapidly growing tumor has resisted medical treatment, and **whenever pressure symptoms arise**. A U-shaped incision is made, sternomastoid muscle drawn aside, and, if necessary, sternohyoid, sternothyroid, and omohyoid muscles are cut. He avoids injuring the capsule of the tumor with knife on account

of hemorrhage. The tissue at upper and outer margin of lobe clamped and divided. Secure superior thyroid artery if is possible. Avoid clamping recurrent laryngeal nerve. Tumor is now dissected away by cutting the attachments to anterior wall of trachea. He leaves a piece of gland, the size of an English walnut, to prevent operative myxedema. Silk is employed to tie vessels. Morphin is administered before or directly after operation to prevent vomiting. Dressings should be loose, but still give support. For this purpose a horse-collar dressing is used, augmented by an ordinary tin internal angular splint to the neck for fixation. The author mentions Reinbach's 80 cases of resection by this method, with a mortality of 3.75%. Author has operated on 2 cases of exophthalmic goiter with unfavorable results. [M.R.D.]

2.—Davis presents a resumé of operations for simple malignant and exophthalmic goiter. Statistics of complications and recurrences are also included. [M.R.D.]

3.—Cumston reports 42 cases of various neoplasms of the thyroid. Excepting the malignant cases, dyspnea was the principal subjective symptom. Most frequently employs the transverse incision of Kocher. A case of sarcoma of the thyroid gland is mentioned, which after operation resulted in general sarcomatosis. [M.R.D.]

Journal of Nervous and Mental Diseases.

December, 1900. [Vol. xxvii, No. 12.]

1. A Case of So-Called Landry's Paralysis with Autopsy. SIDNEY I. SCHWAB.
2. An Atypical Case of Multiple Sclerosis. CHARLES W. BURR and D. J. MCCARTHY.
3. A Case of Malaria Presenting the Symptoms of Disseminated Sclerosis, with Necropsy. WILLIAM G. SPILLER.
4. Note Upon the Occurrence of Multiple Neuritis and Beriberi in Alabama. E. D. BONDUANT.
5. Section of the Posterior Spinal Roots for the Relief of Pain in a Case of Neuritis of the Brachial Plexus. MORTON PRINCE.

1.—Schwab reports the following case: A young married woman, 21 years of age, who had had one stillborn child, and two dying almost immediately after birth, and who for some months had been emaciating, noticed first a tingling and numbness in the fingers of the left hand. A week later the same symptom was noticed in the right hand, then there was gradual weakening of the lower extremities. This gradually increased until there was weakness of all four extremities, and loss of control over the sphincters. There was no fever, no sensory disturbances, no loss of appetite. She died as the result of severe dyspnea. Microscopically, the cord and the peripheral nerves were normal. There was some congestion of the organs, and apparently softening of the heart-muscle. Microscopically, the only important change found was a curious congestion of all the bloodvessels of the cord, associated with old and recent hemorrhages into its substance. There was no degeneration in the an-

terior or posterior roots. Schwab believes that it is possible to explain this condition either by ascribing it to mechanical congestion, or to some toxic process. [J.S.]

2.—Burr and McCarthy report the following case: The patient, a man of 46, had commenced to have difficulty in walking at the age of 39. This gradually increased. His symptoms had been inability to walk without watching the ground, exaggerated kneejerks, ankle-clonus, ataxia and paresis of the lower extremities. Towards the end of his sickness there was extreme spasm of the limbs without wasting or atrophic changes, and no involvement of the arms. Death occurred suddenly, and at the autopsy a condition of multiple sclerosis was found, involving large areas in the cord, and a considerable proportion of the cortex of the brain. The case is interesting because the typical symptoms of multiple sclerosis were never present; that is, there was no intention tremor, no nystagmus, no scanning speech, and no loss of power. The oldest area of sclerosis was limited to the posterior columns in the dorsal region. Later the lateral columns were also involved, and gave rise to the symptoms of ataxic paraplegia, and the subsequent spastic symptom development caused the diagnosis of spastic paraplegia. It is possible that the noninvolvement of the optic thalamus explains the absence of the characteristic symptoms. The changes in the cortex were exceedingly widespread, and even extended to a considerable distance into the underlying white matter. [Although several authorities are mentioned, references have been omitted. J.S.]

3.—Spiller gives a brief abstract of his paper upon a case presenting intention tremor of the left arm, ataxia of the left leg, and transient hemiparesis, affecting first one and then the other side, vertical nystagmus, scanning speech, and exaggerated tendon reflexes on the right side. There was also headache, vertigo, drowsiness, and diplopia. At the autopsy the capillaries of the central nervous system were found to be filled with malarial parasites, and there were numerous small, recent hemorrhages. [J.S.]

4.—Bondurant mentions several epidemics of multiple neuritis that have occurred in various parts of the South. He has obtained reports of various cases of multiple neuritis from other physicians, and has treated 11 himself. In all, 5 had no assignable cause. Beriberi is exceedingly common in Mobile among the sailors, particularly those working on lumber ships. [J.S.]

5.—Prince gives an abstract of his paper, of which the following is the title: "Section of the posterior spinal roots for the relief of pain in a case of neuritis of the brachial plexus, cessation of pain in the affected area; later development of Brown-Sequard's paralysis as a result of laminectomy; unusual distribution of root anesthesia, later, partial return of sensibility." This is a sufficient description of the case. [J.S.]

2. Induration of the Connective Tissue of the Myocardium. K. DEHIO.
3. Second Report Concerning Malaria and Mosquitos on the West Coast of Africa. H. ZIEMANN.
4. A Case of Fatal Parenchymatous Colon Hemorrhage. L. HUISMANS.
5. Traumatic Coma Diabeticum. W. SPITZER.

1.—Landau, while operating on a case of carcinoma of the uterus where it had invaded some of the other organs of the pelvis, found the right ureter involved. The operation was tedious and required over 1 hour; a nephrectomy in addition would have been fatal, therefore he simply excised the malignant portion and brought the two ends of the ureter together; the peripheral portion could not be seen. This was done only as a temporary procedure and he fully expected to perform a nephrectomy when the patient's condition would warrant it, but was surprised to have the patient recover without any complication, and show no sign of hydro-nephrosis. Some time after a cystoscopic examination showed that the right ureter was performing its proper function. This case goes to show that the ureter is not so troublesome

in healing as it is usually thought to be, and that operators must use their own judgment in dealing with these cases. Usually when the ureter is wounded some plastic operation is performed; if it is cut, or a portion excised near the bladder, the end is carried into it; and should the ureter be too short the end is then turned into the bowel. The disadvantage of this is that the bowel soon becomes very irritable. When neither of these operations can be performed the kidney must then be removed. [W.M.N.]

2.—Dehio some years ago made a study of the changes in the heart as a person advances in years, and the publication of his opinion gave rise to contrary ones. Since then he has studied microscopically 36 hearts and still supports his former theories. He divides these cases into 2 groups. 1. Those in which there is an atheromatous or arteriosclerotic change. 2. Those in which the cardiac degeneration is due to sclerosis of the coronary arteries or to impoverished blood, from some chronic poisoning such as lead, alcohol, rheumatism, or after fevers. In cases of hypertrophy and dilation the heart is enlarged, and this increase in size is due to the increase in interstitial substance. In contrast to this there is a diffuse thickening of the heart-muscle due to an increase in the interstitial substance; this he terms myofibrosis. When the heart of a young healthy person is examined microscopically, the muscle will be found bound together by a fine network of connective tissue which is an extension of the subpericardial and subendocardial tissue as well as the adventitia. If this is now compared with that of an older person it will be found that this network has grown thicker, and advance in years renders it more evident, until in old age is quite marked, particularly in a cross-section, where this network can be seen separating the individual muscle fibers; this is evident of a hyperplasia. Although the muscle fiber may have apparently the same thickness as in a young person, there has been some atrophy in it caused by the surrounding connective tissue. This change he terms senile myofibrosis, and is exactly like the former but not of so high a grade. These two forms of degeneration may both be observed in one heart, and where it does occur it is hard to discriminate between them. Myofibrosis is most apt to develop in the walls of the ventricles and in hearts which are hypertrophied and dilated, and to a less extent in dilation. In diseases where the stress falls on the left heart the left ventricle is the usual place where this degeneration is most marked, as in diseases of the aortic valve, while in diseases where the stress falls on the right heart the right ventricle is most affected, as in emphysema. In 10 cases of valvular disease of the heart occurring in young people (15 to 30 years) myofibrosis was in some quite well marked, and in all to some extent. In a case of aortic insufficiency and stenosis of the mitral valve, in a man of 56 years, on the left side it was well developed, and to some extent on the right. Other cases mentioned support the same idea. In 3 cases of phthisis and 2 of emphysema the right heart was more involved than the left. Although this view is not supported by most of the German writers it is by several French authors under the following groups: 1. Sclerose en foyers. 2. Sclerose diffuse rayonnante, or perificulaire. [W.M.N.]

3.—Ziemann describes the weather conditions in Kamerun, Victoria, and Togo. He found that the type of fever, when not previously influenced by quinin, was usually malignant tertian. There were some instances of what were probably continued, irregular, or remittent fever, and he believes that these forms of fever do occur in the tropics in spite of the statements of Koch. He classes the tropical parasites and the estivoautumnal together, because of their size and the size of the segmentation forms. He believes that the tropical parasites, however, are distinctly different from ordinary tertian. He has repeatedly observed cases in which the temperature scarcely rose above the normal, but in which, nevertheless, parasites were found going through their usual course of evolution. These were anemic patients who had already had fever. In still rarer cases the same was observed with the first attack of malaria. In negroes particularly the subjective symptoms of the fever were found but slightly marked in many instances. In many cases one finds marked general depression, with almost complete or complete absence of fever, the symptoms disappearing under the use of quinin. The basophilic granules, which Piehn describes as probably the cause of relapses, Ziemann considers

the results of degeneration. Clinically he considers the prognosis good if treatment is begun early and is energetic. Only 2 cases died. One of them was moribund when first seen, and the other died with severe convulsions, and the cerebral capillaries were found filled with parasites. He did not see the quartan parasite in any of his cases, and ordinary tertian parasites were seen in only one of the cases. His observations in this respect differed largely from those of Koch. He investigated a large series of adults and children among the natives and found splenic tumor and parasites in a very large number of these cases, 23% of both adults and children showing evidences of malarial infection, while of the children below 5 years, 37% showed infection. As many as 75% of the captured women of the Bulis showed infection, and 10% of the children. Splenic tumor was found in 33% of the negroes of Togo. He decides, therefore that the adults in this region did not show complete immunity, but rather an increased resistance, and the children certainly showed no immunity. He has observed cases in which a relative immunity seemed to be acquired, severe attacks giving place to mild ones. In most of the cases in negroes, spontaneous cure took place. He made 7 infection experiments on negroes, and found that in 5 malaria was produced, the incubation period being from 10 to 12 days. This is another evidence that the cases were not completely immune. An interesting observation was that the negroes with malaria often showed marked leukocytosis, the leukocytes being filled with pigment. This leukocytosis probably had something to do with the spontaneous cure. He found no places that could be considered to be free from malaria. [D.L.E.]

4.—Huisman reports a case of **parenchymatous bleeding from the colon** in a boy 12½ years old resulting in death; his family history was negative. A year previous he had a similar attack, and from that time to his present illness he enjoyed good health. The boy was carefully examined and the urine also, but without result; an injection of tuberculin was likewise negative. Coffee-colored stools, with some meteorism, continued without yielding. Treatment consisted in the use of opium, belladonna, bismuth in large doses, ergotin, injections of normal salt solution, etc. The necropsy yielded very little; all the organs were normal except the colon, which showed signs of colitis and was dark colored; ameba and anchylostoma were not found, and the blood was also normal. [W.M.N.]

5.—After a brief general review of the question of **diabetic coma and its causation** Spitzer describes a case in which there had never been any previous signs of acid intoxication, and only a mild glycosuria that was readily kept within limits. The patient, a professor, broke his clavicle. He was intensely excited by this, and the same day the glycosuria increased largely, albumin appeared in the urine, and the next day acetone and diacetic acid were present. Large amounts of alkalies were given and there was some improvement in the condition, but 6 days after the injury there was still some obscuration of the intellect, increasing restlessness, and persistence of the diacetic acid reaction; the next day the symptoms increased rapidly, and 2 days later the patient died in deep coma. There was no evidence of the presence of oxybutyric acid in the urine. The shock of the injury is believed to have brought on the fatal acid intoxication and coma by increasing the glycosuria. Spitzer is of the opinion that in both normal and diabetic persons the products of the breakdown of the carbohydrates enter into union with the abnormal acids produced from the albumins and fats, and prevent abnormal synthetic combinations of the oxybutyric acid and thus shield one from acid intoxication. The increase in the glycosuria was an evidence of increased imperfection in the assimilation of the carbohydrates, and, he believed, by preventing the breakdown of the carbohydrates the shock thus led to acid intoxication. [D.L.E.]

Neurologisches Centralblatt.

1. The Significance of the Scapulohumeral Reflex. VON BECHTEREW.
2. Imperative Vomiting. VON BECHTEREW.
3. The Subjective Response of the Colors of the Spectrum. H. SOLOMONSOHN.

4. Clinical and Experimental Contributions to the Question of the Secretion of Tears. G. KÖSTER.
5. The Destruction of the Pyramidal Tracts after Decussation. M. ROTHMANN.
6. The Neurosis of an Area of the Cervical and Brachial Plexus as a Result of a Diseased Tooth. F. HESSE.

1.—Von Bechterew, in reply to Haenel, contends that the **scapulohumeral reflex** is not a manifestation of myotactic irritability, but is really a periosteal reflex. He admits that its loss or diminution is of no clinical significance. On the other hand, its presence or exaggeration is practically of the same value as the presence or exaggeration of any of the other reflexes in the upper extremity. Haenel himself admits that it was present in 43.4% of his cases. [It appears to have escaped the acute observation of von Bechterew hitherto, that there are really 2 types of this reflex; one in which the arm is abducted, and slightly rotated, as a result of the contraction of the infraspinatus, and another, in which the reflex action is much more extensive, and involves contractions of the trapezius and deltoid, and therefore the abduction of the arm. The latter type apparently occurs only in cases in which the pyramidal tracts are diseased on the same side, and we have been able to demonstrate it in a number of cases of hemiplegia. The first form may, in conditions that give rise to increased muscular irritation, be greatly exaggerated. [J.S.]

2.—Von Bechterew reports two interesting cases. The first, a man whose occupation was singing in concerts. On one occasion on appearing before his audience, he had a slight tickling in the throat, followed by a feeling of nausea. On every subsequent occasion, upon his first entrance upon the stage, this feeling of nausea has recurred, and in some cases has been followed by vomiting. He affirmed that the consumption of a little cognac just before leaving the wings, would at least render the symptom milder, but it has gradually required more cognac in order to overcome the disability. The second case, a woman of 28, suffers from nausea every time she leaves her dwelling; this is followed by palpitation of the heart, and fear lest she should vomit. Not infrequently the attack terminates with profuse perspiration, on which occasion there is actual vomiting. This patient has also found that cognac is a valuable prophylactic. Examination of the patient failed to reveal anything excepting an exaggeration of the tendon and cervical reflexes. There is a distinct neuropathic heredity. Treatment directed to the heart with bromids and caffeine cured the patient. This form of *imperative* vomiting is similar to imperative blushing, and represents a mental condition that is manifested by a motor reaction on the part of the smooth muscle fibers not under the control of the will. [J.S.]

3.—Solomonsohn divides the causes of **chromatic vision** into extraocular and intraocular. The former are due, of course, to local variations in the atmospheric refraction. The latter may be physiologic or pathologic. In either case we may have a halo about the flame, composed of the spectral colors, or a circle, separated from the flame by a black area. The first form under pathologic conditions occurs as a result of the irritation of the eye; the second, particularly in cases of glaucoma. The communication of Adamkiewicz in a previous number of the *Centralblatt*, therefore neither describes an original observation, nor is the explanation given by that author of any value. [J.S.]

4.—In the course of his studies of Bell's paralysis, Köster has noted the following changes in the **secretion of tears**. Hypersecretion occurs only as a manifestation of irritation, and never as a paralytic phenomenon. It is much rarer than parietic secretion. The method of estimation was as follows: A piece of filter-paper of definite size was placed in the conjunctival sac of each eye, and then the mucous membrane of both nostrils tickled with a camel's-hair brush. In about 10 minutes the secretion of tears ceased and the amount secreted on either side could then be estimated by weighing the paper. The point in the course of the facial nerve at which the fibers going to the tear-ducts leave, was then determined by exclusion, to be in the neighborhood of the geniculate ganglion, or above it. The trigeminus apparently acts only reflexly, and therefore the facial nerve is probably the excitomotor element. Experiments on dogs, monkeys and cats, however, showed that in spite of destruction of the facial nerve downwards to the geniculate ganglion the lacrimal and

superficial petrosal nerves did not degenerate, and it therefore is necessary to assume that the sympathetic fibers possess an influence upon the tear secretion. [J.S.]

5.—Rothmann not satisfied with the Starlinger operation for the destruction of the pyramids in the medulla, has devised the following operation for the **destruction of the pyramidal columns after decussation**. The neck is incised on the right side of the larynx, the anterior obturator membrane exposed and incised, and the dura opened from the occipital bone to the edge of the atlas. The needle is now inserted in the middle line, and moved up and down as far as the bone allows. The animals sustain the operation well, and can be kept alive for almost an indefinite period of time. Hemorrhage is exceedingly rare, and even when it does occur, apparently is not fatal. The results show that with the exception of the pyramids and the anterior ground bundle the columns of the cord remain intact. [J.S.]

6.—Hesse reports the case of a girl who, in 1895, bit upon a shot, causing severe pain in the tooth. Subsequently there were pains in the upper and lower jaws, that soon extended to the right shoulder, breast, and arm. The duration of the attacks varied from $\frac{1}{2}$ hour to 4 hours. The exciting causes were emotional disturbances, warm or cold fluids in the mouth, or sudden jarring of the body. Two months after the **injury to the tooth, paralysis** developed in the right arm. The tooth was still painful, and as a reference to the clinical reports showed that the pulp had been exposed during filling 6 years before, it was decided to extract it. The pulp was found gangrenous, and there was some periostitis about the roots. For the first 3 weeks the pain was still present, but much milder, and after that it disappeared completely. [J.S.]

42.—The cause of **inflammation of the pancreas** is generally a bacterial infection of the parenchyma of this gland. So long as the inflammation is limited to the gland itself the clinical symptoms are not characteristic enough to differentiate it from other diseases of this part of the human body, such as gallstones or gastric ulcer. Pronounced symptoms usually first appear when the inflammation has spread to the peritoneum or to the retroperitoneal tissues and even then the etiology of the case is most uncertain. Necrosis of the pancreas is most commonly caused by hemorrhagic infarcts developing as a result of the inflammation. The hemorrhages which are found around the gland are likewise a secondary process and are due to erosion of the bloodvessels in the necrotic areas, and for this reason are most apt to undergo suppuration. The symptoms of shock and collapse which so frequently occur during the course of acute pan-

creatitis are due to infection of the peritoneum which most commonly takes place through the perforation of a suppurative center into the abdominal cavity. Sometimes necrosis of the pancreas will bring about a septic peritonitis without exudate which rapidly proves fatal just as in necrosis of the appendix. More frequently the infection of the abdominal cavity remains limited to the bursa omentalis and the abscesses arising therefrom do not spread from the immediate neighborhood, so that a diagnosis of the same can be made and proper treatment instituted. The symptoms of intestinal obstruction which so frequently occur in acute pancreatitis are due to effusions into the sac of the omentum which cause irritation of the peritoneum. Operating in the acute stages, that is, when there are symptoms of an acute and diffuse peritonitis, is to be rigorously avoided. The fat necrosis is a consequence and not a cause of the pancreatic inflammation and is due to the action of the pancreatic secretion and an unknown accompanying agent on the fat cells. Diabetes appears when the pancreas in whole or part has been destroyed and when the remaining bits of gland have been rendered incapable of carrying on their normal functions because of shrinking, etc. [G.B.W.]

44.—Riese reports 2 interesting cases of **thrombosis of the venous sinuses of the dura mater**. The symptoms of the first case lead to a diagnosis of thrombosis of the cavernous sinus caused by an orbital inflammation which had developed from an empyema either of the maxillary antrum or of the frontal sinus. The opening of these two cavities, however, failed to reveal the presence of pus, but a large abscess was found lying to the side of the pharynx. The patient died within an hour after the operation. The post-mortem showed the presence of a suppurating thrombus of the cavernous and circular sinuses, and it seemed most probable that the course of infection had been as follows: From the original infection in the periosteum of the alveolus of the last molar tooth, it had spread to the neighboring tissues of the pterygoid fossa, thence to the pterygoid plexus of veins and from here direct to the cavernous sinus through the veins in the foramen ovale or through the middle meningeal vein. The veins of the orbit contained only post-mortem thrombi. The second case was similar in that the cause of the thrombus was an alveolar periostitis, but the patient recovered in the latter, thanks to an extensive operation by means of which almost the entire clot was removed. In this case the direction taken by the thrombotic process was first to the facial vein from some periosteal venous branch and thence to the internal jugular along which the clot readily spread to the transverse sinus. [G.B.W.]

45.—Rubinstein says that, according to his experience, when a bone is broken as the result of **direct force**, the fracture is of a triangular shape, provided the **fractured bone** is broad or flat in form or at least possesses one or more flat surfaces. The force which causes these fractures is generally applied when the bone is supported by some firm surface, just as a stick held by one hand is readily broken off by the other. He reports 6 typical cases. [G.B.W.]

46.—Rotter reports 4 cases of **inflammatory stricture of the sigmoid flexure and of the rectum**. The character of the cases were such as to demand the formation of an artificial anus, but in all but one the patient died soon after the operation. In the one successful case the patient was enabled to renew his work and by means of an enema had a fecal movement through the artificial opening every second day. The cause of the formation of cicatricial strictures in the lower rectal segment is found in the existence of complete and incomplete rectal fistula which had often existed for years. The development of the inflammation which leads to the later cicatricial contraction is explained as follows: the colon, from pressure of gas and feces becomes distended, and the openings through which the bloodvessels gain access to the mucous membrane are enlarged, so that the mucous membrane is by the internal pressure forced through them as multiple diverticulums. Masses of feces gain access to these diverticulums and by mechanical pressure and obstruction cause ulceration and perforation of the wall of the diverticulum. [G.B.W.]

48.—Von Bergmann says that the presence of a loop of intestine distended with gas can be diagnosed by simple inspection and palpation only when the large intestine is involved and then not always. Also the knowledge of the position of a distended loop is not of much service in locating

the point of obstruction, as it is very rare that the strangulated loop is the only portion of the gut distended. And again the palpation of a loop of the intestine, either distended with gas or rendered firm by peristaltic contraction, is of little importance in constriction, if the firmness disappears under narcosis. In speaking of operating he says that when it is necessary to resect, the Murphy button possesses the advantages of allowing an immediate passage of the intestinal contents in the proper direction and also prevents the distention of the freshly united surfaces from the pressure of the gas. In a few rare cases, however, an unusual amount of necrosis of the intestinal wall results from the use of the button, causing a perforation. He reports 126 cases of **intestinal obstruction** from his clinic and has arranged them into groups and sub-groups. [G.B.W.]

49.—Freudenberg says that **Bottini's operation** for enlarged prostate is not quite so dangerous a procedure as is generally supposed. He has collected from different sources some 683 cases which show a mortality of 5½%. In 666 cases the results, as far as the benefit of the operation is concerned, are as follows: No benefit in 6½%, more or less benefit in 88%, and of these latter ¾ were cured, so that the patient could urinate normally, while the other ¼ were only slightly improved. Freudenberg, in operating, at first incised the prostate with the bladder empty, but having a fatal case of peritonitis develop from burning through the bladder-wall, he adopted the method of having the bladder filled with fluid. At present, however, he inflates the bladder with air and has obtained just as good results with less current as when a fluid was used. In the after-treatment he has stopped using continued catheterization, except in cases of hemorrhage, very purulent urine, and when frequent catheterization is necessary in cases because of difficulty or pain. When the results following the first operation are not satisfactory the surgeon should not hesitate to repeat the cauterization at another sitting. The chief reason for failure to obtain good results is a lack of thoroughness in the operation, especially in the length of the incision. The length of the cut differs with the case, but it should not exceed 4½ to 5 cm., and generally from 2½ to 3½ cm. will suffice. To measure the proper length for the incision, after introduction of the instrument, the beak is turned backwards and the finger in the rectum measures the distance from this to pars membranacea, and ¼ of this distance will represent the proper length for the posterior cut and ½ for the lateral. He describes a new modification of the instrument in general use for which he claims almost perfection. [G.B.W.]

50.—Mangoldt reports an interesting case of **defect of the larynx**, covered in by transplanting a small piece of costal cartilage over the opening. The patient had originally suffered from the presence of numerous polyps in the larynx and the removal of these by thyrotomy had given rise to marked stenosis of the larynx for the relief of which 4 tracheotomies had, during the course of time, been performed. Finally the stricture was overcome, but an extensive opening remained in the larynx. This was closed by turning a flap of skin from the side of the neck over the opening with the epidermis facing the lumen of the larynx. The raw surface which was left facing outward was covered by a second flap taken from the front of the sternum, and which included a bit of cartilage from one of the ribs. The result was very satisfactory and the piece of cartilage prevented the skin from sinking inward during inspiration. A second case of laryngeal stenosis was treated on a much similar plan, except that the operation was done in 5 stages and a flap consisting of 2 layers of skin with the rib cartilage between was first made before the larynx was opened. The larynx was split and the flap so arranged that the cartilage came between the separated edges. The result was also good. In another case, one of syphilitic saddle nose, a bridge for the nose was made by slipping a piece of costal cartilage with its perichondrium attached under the skin over the nose through an incision at the glabella. The cartilage healed in all right, and after a second and correcting operation the patient had quite a presentable nose. [G.B.W.]

51.—Von Angerer says that during the past 4 years there have been 9 cases of **subcutaneous rupture of the intestine** operated on and only 2 cases recovered. Rupture of the intestine from contusion of the abdomen resembles quite closely perforating wounds of the abdomen as far as the treatment is concerned, but differs radically in that the latter

is comparatively easy to diagnose while the former is most difficult, especially in the early stages when operation will still be of benefit to the patient. Early diagnosis is of course most important in order that the abdomen may be opened and the ruptured intestine treated. After 24 hours have elapsed there is little hope to be had from operating, and the later the operation is delayed the greater are the chances of the patient dying. As to the symptoms which will enable an early diagnosis to be made: First, the kind of injury is important, a localized force such as imparted by a horse's hoof or by a stick is more liable to cause rupture than is a general contusion. In cases where the symptoms of shock do not during the course of a few hours tend to ameliorate or when they, instead of decreasing, increase, something more than pure shock should be suspected. The pulse is always an important indication, though the increase in frequency may not come on until several hours after the accident. The cessation of abdominal breathing is an indication of trouble. Vomiting coming on immediately after the injury and especially when it increases in severity is an almost positive sign of some lesion to the intestinal tract. Pain is an important symptom when it increases in severity, but many cases of intestinal rupture exist without any pain being complained of. Narcotics should be avoided in these cases because they tend to hide important symptoms, especially that of pain. Meteorism and the disappearance of normal liver-dulness are not such important symptoms as is generally supposed, because intestinal rupture often exists without either of them being present. A rigidity of the abdominal muscles is an important sign of peritoneal irritation and consequently is indicative of intestinal rupture. Paralysis of peristalsis results from contusion of the intestines and is manifested by the passage of neither flatus nor feces. Urination is also somewhat hindered. The treatment of subcutaneous rupture of the intestine should consist in operation at the earliest possible moment even when there is no *positive* proof of the lesion, but only a strong suspicion of its presence. Delay means septic peritonitis. The abdominal incision should be large enough to allow of an easy examination of the whole of the intestine as the ruptures are most apt to be numerous. If there is much contusion around the tear, or several tears exist in close proximity to each other, resection will often be the simplest way of treating the gut. When peritonitis already exists the intestine should be inspected outside of the abdominal cavity and the general cavity flushed with sterile normal salt-solution. [G.B.W.]

52.—Von Eselsberg reports a case in which he **replaced the index finger** of the right hand, which had been lost through accident, by **transplanting the second toe** of the right foot. The method adopted was that of Nicoladoni, which is briefly as follows: A square-shaped flap of skin was raised from the dorsal surface of the foot over the region of the second tarsophalangeal joint. The dorsal tendons were then cut, the joint opened, the cartilage removed from the end of the phalanx and the flexor tendons divided. The stump of the first finger having been prepared the hand was approximated to the foot; the palm of the hand to the dorsum of the foot. The flexor tendons of the toe were united to the flexor tendons of the finger, the bone of the toe was fastened to the bone of the finger by a silk suture passed through drilled holes, the extensor tendons united and the flap of skin from the foot stitched to the back of the hand. The parts were held in position by a plaster-of-paris dressing for 12 days, at the end of which time the nourishing pedicle on the sole of the foot was cut through. The wounds healed promptly both on the foot and the hand. The functional result, however, was almost nothing up to the present writing; sensation was noticeably lacking. [G.B.W.]

53.—Friedrich in a series of experiments on rabbits has shown that the removal of portions of the **omentum** or ligation of some of the omental bloodvessels is very apt to be followed by multiple anemic and hemorrhagic infarcts of the liver. This often happens even when very small portions have been ligated and when as much as ¼ or ⅓ of the whole omentum is included. The infarcts develop in almost every case. When the ligated area includes the arteria epiploica, in many cases, there will also be one or more gastric ulcers formed. Whether a true ulcer or only a hemorrhagic infiltration of the mucosa is present depends on the length of time elapsed after the ligation of the omentum. The position

of the ulcer corresponds to the distribution of the arteria epiploica inferiores. [G.B.W.]

54.—Rhen says that in **operating on the rectum** even in extensive resections, one should avoid wounding the sacrum. It is perfectly practicable to remove carcinoma of the rectum even when placed high up, through incisions in the perineum or vagina, the operation being as easily performed as by the older method of resecting a portion of the sacrum. The rectum should be loosened extrafascially, *i. e.*, the rectum and its fascia should be dissected free from the surrounding tissues together. A high amputation should be done in all cases, in the epithelioma of the anus, as well as in those cases where the neoplasm is placed higher up. The sphincter muscles should, when possible, be retained, though the mucous membrane of the anus may be sacrificed. When the growth occupies the pelvic colon the combined abdominoperineal method may be of great service. [G.B.W.]

55.—Sprengel reports a case of **intussusception** caused by a congenital cyst of the intestinal wall, presenting symptoms which lead to the diagnosis of tubercular peritonitis. At the operation an invagination of the small intestine into the colon was found and though the disinvagination was easily accomplished, 10 cm. of the large and 6 cm. of the small intestine were resected. An end-to-end anastomosis was done with a Murphy button and the abdominal wound closed. The recovery was uneventful. The method which yields the greatest hope for a permanent cure in these cases of intussusception in which the mesentery is very long and there exists a great liability of a recurrence, is resection. Fastening the intestine to the posterior wall of the abdominal cavity does not afford an equal amount of security. The exciting cause of the invagination in this case was the presence of a congenital cyst located in the ileocecal valve. The cyst was undoubtedly derived from the intestinal tract as shown by the presence of mucous membrane, elements of lymphatic tissue, and the presence in its walls of muscular fibers, but whether it was the result of some change in the ductus omphalo-mesentericus or other embryologic abnormality, it is impossible to say. [G.B.W.]

56.—Anschutz report a case of **ectopion of the bladder** practically cured by covering in the defect with an isolated portion of the colon. The steps of the operation were carried out at different times, making 4 operations to complete the procedure. At the first, the abdomen was opened just above the bladder and 12 cm. of the large intestine in the neighborhood of the cecum was isolated from the rest of the intestinal tract. One end of the isolated piece of gut was closed and the other fastened to abdominal incision. At the second, the upper edge of the bladder was fastened to the lower margin of the isolated bit of intestine. At the third a plastic operation was done on the penis to make a urethra. At the fourth the intestine was brought down over the bladder and sutured there, and after the skin had been brought over the whole field a continuous cavity was made from the meatus to the top of the new bladder. After the wounds were healed the patient was in a greatly improved condition, being able by means of a spring which mechanically compressed his urethra to control the flow of urine. No excoriations or other discomforts developed and the urine, except for an excess of mucus, became normal in character. Anschutz says that this operation should not be undertaken as a radical procedure when the ectopion is seen early in life; it is adapted rather to remedy a bad state of affairs when adults present themselves for relief from this affliction. [G.B.W.]

21.—Lapinsky believing that a pure **anemia of the limb** might give symptoms differing somewhat from those produced by ligation of the limb, has performed a number of experiments chiefly upon rabbits. The technic consisted of the occlusion by ligature of the main arteries of the limb. The artery selected was the left common iliac and in addition the small arteries of the intestinal wall were also ligated. In one case the collateral circulation was not established for 5 days, and in the others it appeared in 4 days or less. The first animal was killed and the tissues examined microscopically. The symptoms were interesting. The limb became suddenly cold, **paralyzed**, passive movement was unaffected, there was complete anesthesia at the end of the first hour, loss of the cutaneous and tendon reflexes and rapid quantitative diminution to electricity commencing during the first hour. Typical reactions of degeneration did not, however, appear in the muscles. These changes appeared to be due to lesions of the nerve, those of the muscles, consisting of acute cloudy swelling, being apparently less important in the development of the symptoms until comparatively late in the disease. Microscopically, changes were observed in the myelin sheaths and the axis cylinders of the nerves. [J.S.]

22.—Ransohoff has had the opportunity to **study the spinal cord** and a portion of the brain from a woman that died at the age of 66 from an uncontrollable hemorrhage from the bladder due to a carcinoma. He found areas in the spinal cord in which the axis cylinders were greatly swollen and presented the appearance of the hydropic softening described by Minnich. The neuroglia in these areas also showed a moderate degree of proliferation. Compound granular cells were not present in the tissues. In the brain there were numerous minute hemorrhages in the cortex, associated with slight hemorrhagic inflammation. The changes in the spinal cord resembled very closely those found in progressive pernicious anemia, and taken in conjunction with those of the brain indicate that the process depends upon some primary lesion in the bloodvessels, probably multiple thrombosis. The changes in the white matter of the spinal cord are probably to be explained in the same manner. The only clinical symptom which can be ascribed to these alterations was probably the period of stupor that existed for 6 days before death. It is possible, however, that in more acute stages these changes would lead to psychoses. There was some heterotopia in the spinal cord, probably associated with a chronic imbecility with which the patient was affected. [J.S.]

23.—Sander has examined the spinal cords of 25 persons all dying at an advanced age. Macroscopically changes were found in the brain. In the spinal cord he observed the disposition to calcareous plates in the membranes. Microscopically, the myelin sheaths were somewhat paler, and here and there areas of degeneration were observed, that, when stained by the neuroglia method, were found to be entirely sclerotic. The cells showed an excess of pigment, and were often deformed. The neuroglia was proliferated. The bloodvessels showed the ordinary senile changes. There was no proliferation of cells in the tissue, although the process was probably chronic. Numerous areas of fresh degeneration may be observed, and in these spider cells are quite common. The process resembles rather closely that found in pernicious anemia, and is probably identical with the changes already described in paralysis agitans. He divides his cases into 3 groups. First, a mild form with slight diffuse loss of myelin sheaths, with slight secondary proliferation of the neuroglia, and moderate degeneration of cells. Second, a severe form with diffuse degeneration of the myelin sheaths, the appearance of foci of pronounced sclerosis and severe degeneration of cells. Third, a presenile form with acute processes and numerous foci. These can probably be best termed the arteriosclerotic degenerations of the spinal cord. [J.S.]

24.—Petrén has observed 285 cases of **neurasthenia** in the last 5 years in a service of 2,478 cases; that is to say, about 11.5% of all patients presenting themselves. Of these, 141 cases were men and 144 cases were women. All classes

of men were about equally affected, but there were less than half as many women in either the upper or middle class as in the lower class. It therefore appears that among the laborers the disease is practically as common among women as among men, and the explanation is to be found in the fact that the women of those classes are compelled to work quite as hard as the men physically, and are subjected to the same or even greater sources of mental strain. The causes of the disease in the lower class were various and in general were the same as those that have been generally accepted as etiologic factors among the upper classes. Among the more important were sorrow at the death of a relation or for similar personal reasons; anxiety as a result of financial loss or difficulty in obtaining nutrition; overexertion, chiefly intellectual in character; and some infectious disease, chiefly influenza, although Petren doubts that this is as serious as is commonly believed. He believes that depressing psychical influences are the most important features. Nevertheless, as all persons are exposed to these influences and only a certain proportion develop neurasthenia, he is convinced that there must be some hereditary predisposition, and he is rather inclined to suppose that alcoholic excesses on the part of the parents are of considerable weight. Improved hygienic conditions probably have a tendency to diminish the disease. It occurs very commonly among the peasants whose mode of life has not changed particularly. It is probable that the disease has always been endemic in the rural districts. He calls attention to 2 or 3 minor points. The more rapid the development of the disease the better the prognosis. It is usually associated with some other disturbances in the general condition, particularly an unsatisfactory nutrition. It is possible that occasionally it is the result of arterial sclerosis; at any rate 2 cases are reported, both men of 59, who had typical neurasthenic symptoms and moderate sclerosis of the arteries. In the second case there was a distinct history of neurasthenia in the father. In 4 of 16 cases that he carefully investigated for hyperesthesia of the skin the result was positive, and the hyperesthetic areas were found, once on the outer side in the epigastrium and 3 times on the left side in the epigastrium. [J.S.]

25.—Haenel reports an interesting case characterized by the gradual development of left-sided **paralysis**, and peculiar disturbances of sensation involving the whole of the left side; at the same time there was complete paralysis of the muscles supplied by the third nerve on the right side, and involvement of the fifth nerve in both its motor-sensory portions on the left side, the left facial, auditory and glossopharyngeal nerves on the same side; the muscles of the left side were spastic; the gait was correspondingly altered, and there were slight indications of ataxia; there was disturbance of equilibrium, and a tendency to fall toward the left; ataxia was not evident, although when the patient was recumbent there was complete anesthesia in the left hand; there was mimic paralysis of the left side of the face. The lesion is readily located in the right **crus**; the center was probably situated in the fillet, it then probably extended downward, involving the motor portion of the **pyramidal tract**, but evidently in the fibers passing to the hypoglossal nucleus escaped; it evidently extended also to the nuclei of the oculomotor nerve. The course of the lesion was peculiar: the sensory disturbances occurred first, and were most persistent, but in the course of time complete recovery occurred in the motor symptoms. It is difficult to understand either the nature of the lesion, or the changes that occurred in it. Three of the symptoms are of particular interest. The disturbance of equilibrium was evidently caused by the lesion of fibers passing to the **cerebellum**; the mimic paralysis, by involvement of the fibers of the thalamus; the anesthesia of the hand by an interruption of the cerebral fibers of sensibility. Haenel suggests that this type of anesthesia is due to the greater vulnerability of the fibers contained in the fine coordinating movements of the extremities, not to their distinct anatomic position. [J.S.]

26.—Bach contributes an article of exceptional value based partly upon some careful experimental and histologic work of his own, partly upon careful collation of the work of other experimenters in this field. He produced eversion of the eyeball upon various animals, pigeons, rabbits, cats, and monkeys, and also studied the brain of a man who had been blind in one eye for a number of years. It is impossible to do more than give a brief summary of his con-

clusions. In the pigeon there is total decussation of the fibers of the optic nerve; in rabbits, cats, apes, and men, about one-third of the fibers do not decussate; there is apparently no direct communication between the optic fibers going to the corpora quadrigemina and the oculomotor nucleus, nor between the optic fibers and the centers in the cervical cord and medulla that govern the movements of the pupil. The **pupillary fibers** that decussate in the chiasm, decussate again further back in the brain; this is proved by the **homolateral pupillary reaction** that occurs in animals that have total decussation of the optic nerves. The descending pupillary reflex tract from the primary optic ganglia to the medulla, is probably a portion of the fillet; the ascending tract to the oculomotor nucleus is almost certainly the posterior long tract. It is not necessary to accept an intimate anatomic relation between the cells for the sphincter muscles of the pupil in the oculomotor nucleus, and the various centers. [J.S.]

27.—Nalbandoff reports a case of **syringomyelia** that is interesting chiefly because there were present curious alterations in the bone that have not hitherto been described. The patient, a man of 31, had been normal until 27 years, although premonitory symptoms had preceded this period. The disease probably commenced in the left shoulder; from time to time there was severe pain and swelling, and later a considerable amount of pus was evacuated, but a subsequent incision was painless; later, repeated incisions were necessary. As the result of a slight wound to the thumb, the part commenced to swell, an abscess formed around the nail, which was lost; the thumb then began to enlarge considerably. The symptoms of syringomyelia were characteristic. Nalbandoff discusses particularly, the alteration in the thumb; although the bone was uninjured, it was softer, and as it failed to produce a shadow with the Röntgen-ray, there was probably a decalcification. It is impossible to find a satisfactory explanation for this, but it is not likely that it was the result of the abscess. [J.S.]

9.—1. Stieda reports an interesting case of **occlusion of the intestine** at the duodeno-jejunal junction. The most important points gathered from a consideration of the case were the following: That chronic dilation of the stomach connected with sinking of the small intestine into the pelvis, probably cannot of itself lead to occlusion of the intestine by twist in the mesentery. This condition is much more likely to be due to acute atony of the stomach or of the duodenum. As this atony is really the cause of the acute obstructive symptoms, it should be termed acute gastric dilation of the stomach. The symptoms are very prone to occur after operation, especially on the bile-ducts. In every case in which severe and continued vomiting occurs, the surgeon should think of the possibility of gastric complications. The treatment of these cases should be the institution of a proper prophylaxis. When other means fail, the performance of gastroenterostomy should be considered. 2. This case of **phlegmonous inflammation of the stomach** occurred in a woman of 24. An operation was

done for gastric disturbance which had lasted for 2 years or more and consisted of pain and vomiting, the vomiting often consisted of "coffee-grounds." At the operation a hard tumor was found in the region of the pylorus, almost the size of an apple. Gastroenterostomy was performed, and the abdominal wound closed. Seven days after the operation the patient died. At the postmortem the suture line was found intact, not allowing any leakage. On opening the stomach an ulcer was found in the region of the pylorus, which was surrounded by a diffuse swelling of the entire thickness of the extract wall. An anatomic diagnosis was made of carcinomatous ulcer of the pylorus, with phlegmonous gastritis and purulent peritonitis. 3. **Hernia** in this case was first noticed 15 years ago. Less than a year ago the patient experienced severe pains in the region of the rupture, and on removal of the truss, which for some time had not held up the hernia as it should, the tumor was seen to be markedly enlarged and had spread into the right labium majora. At the operation, the hernia was found to be femoral and had pushed its way up under Poupart's ligament until it gained a position in the labium majora. The operation was completed after the method of Bassini, and the patient made a good recovery. [G.B.W.]

10.—Koltze reports a case of **complete extirpation of the tongue and floor of the mouth**. The patient was a man of 53. In September, 1898, a tumor developed on the point of his tongue. This was removed by Langenbeck's method, of sawing through the left side of the lower jaw. The growth, however, returned by June, 1899, and had developed to such an extent that it was considered inadvisable to operate. When examined by Rose, the tongue was found thickened, the left side more than the right, it was wrinkled and hard, and the swelling could be traced clear to the base of the tongue. The posterior portion of the tongue closely approached the soft palate, and the anterior almost touched the upper incisor tooth, so that the patient was forced to keep his mouth open the greater part of the time. Operation was done under chloroform narcosis. An incision was carried through the entire thickness of the under lip down to the bone; another cut running at a right angle from the first was carried along the edge of the lower jaw to the left angle of the mandible. A skin flap was turned upwards from the lower jaw, carefully avoiding the mucous membrane, and an exarticulation of the left side was done. The horizontal incision was then carried toward the right angle of the jaw, and the latter sawn through with a chain saw just below the ascending right ramus. The vessels were tied as soon as they were cut, including both lingual arteries and the left facial artery. Starting from the left side of the wound, the tongue, with its adjoining infiltrated tissues were cut away with scissors and knife, and that portion of the tongue and floor of the mouth still in connection with the hyoid bone was removed with Chassaignac's ecraseur, just immediately in front of the epiglottis. The diseased tonsils were removed. The mucous membrane of the epiglottis was then stitched to the remains of the mucous membrane of the under lip, and after removal of an inch or more of the soft parts of the chin, the skin of the two sides of the wound was sutured together. Feeding of the patient after the operation was done through a tube introduced by himself. In 9 days the external wound had healed, and the granulated surface in the mouth had become much smaller. Fifteen days after the operation the patient left the hospital. The patient could swallow better than before the operation, and speech was also improved. [G.B.W.]

11.—Böttcher has written an elaborate article on **hepatopexy**, considering the subject from a clinical standpoint, and he ends his article with the following conclusions: (1) In cases of hepatoptosis, the only real cure is to be obtained by the performance of hepatopexy; (2) in hepatic anteversion, that is partial hepatoptosis, hepatopexy should be done when other treatment has failed to set aside the severe symptoms; (3) in constricted liver found in persons who lace tightly, hepatopexy should be chosen in preference to resection; (4) in cases of uncomplicated hepatoptosis, splendid results may be obtained by the performance of hepatopexy; (5) when the hepatoptosis is only a part of a general splanchnoptosis, the simple hepatopexy is not indicated,—in this condition a general reconstruction of the abdominal wall as performed by DePage offers the best hope of success; (6) in those cases in which the hepatoptosis has been caused by

disease of the gallbladder in which there is a marked constriction of one or more lobes of the liver, or in which one of the lobes is floating, or in which chronic disease of a greater part of the liver is present, the cholecystotomy will afford better chances of success if preceded by hepatopexy; (7) in order to cure or to at least relieve the symptoms caused by partial hepatoptosis, it is not necessary that a complete reposition of the movable portion of the liver should be made,—immobilization will accomplish just as much; (8) in order to produce permanent fixation of a movable liver, the effort should be made rather to produce adhesions than to fasten by sutures. [G.B.W.]

13.—In speaking of surgical treatment of **enteroptosis** in general, we must remember that the movable viscera, such as the intestines and stomach, cannot be fixed firmly to a stationary support in the same way that we would stitch a kidney back into the lumbar fossa. Therefore, an ideal gastropexy for the relief of gastropoptosis should consist in the shortening of the normal supports, which, by their lengthening, allow the viscera in question to move and drop forward into various malpositions. Bier's method of operating on these cases is briefly as follows: Three or 4 sutures are passed just below the liver through the ligamentum gastrohepaticum in such a manner as to produce folding—therefore, a shortening of the ligament when they are drawn upon and tied. The shortening of this ligament brings the displaced stomach back into its normal position. The first suture is placed close to the ligamentum hepatico duodenale and includes the serous and muscular coats of the pylorus and the capsule of the liver. The remaining sutures are inserted in a direction towards the cardia. Blecher reports 4 cases in which this operation was carried out by Bier, and another case of colonoptosis in which the mesocolon was shortened in a very similar manner. In regard to indications for operating in cases of enteroptosis, Blecher concludes that all cases of floating or movable kidneys, which cause more or less distressing or serious symptoms, should be operated upon and the offending organ firmly fixed in its normal position. Enteroptosis does not demand operation in the earlier, or what might be termed, latent stages. Operation, however, is indicated when the ptosis is marked and the use of various abdominal binders are apparently valueless; various internal medications and dieting leave the condition unchanged. [G.B.W.]

14.—Kredel reports an interesting case of **congenital absence of the important muscles of the neck**. The patient, a girl, when last examined, was 10 years of age. She possessed a marked cleft palate, was of rather delicate build and showed an increasing scoliosis. The deformity caused by the absence of the muscles of the neck was a high position of the shoulders, an unusual curving of the clavicle, and thinness of the neck itself. There was complete absence of the sternomastoid on both sides, though electrical stimulation caused a muscle bundle, about 2 mm. thick, to stand out on the left, which perhaps was a rudiment of the left sternomastoid muscle. Both trapezium muscles were also absent in the back between the shoulders, as well as in the neck, and no trace of the omohyoid could be discovered. The anterior muscles of the neck, that is sternohyoid and sternothyroid, were present, and indeed hypertrophied. Perhaps the most surprising part of the whole case was that there was practically no disturbance of function, all normal movements of the head being apparently retained. [G.B.W.]

15.—Frank has made a series of experiments on dogs in endeavoring to discover a method of **establishing an opening between the bladder and rectum**. The results he obtained are important clinically, because of their application to cases of exstrophy of the bladder. The operation consisted in making an incision in the lower part of the abdomen, drawing forward the bladder and rectum and performing an anastomosis by means of a resorbable button. The button consisted of decalcified bone. Out of 15 dogs thus operated upon, 9 recovered and 6 died. He says this operation would be more favorable in men, because of the ability of carrying out proper after-care and treatment. The advantages claimed for this operation are: (1) The easy execution and the shortness of the time of operation; (2) the lack of danger of ureteral stricture through cicatrization and the absence of the possibility of necrosis; (3) the proportionately small danger of infection; and (4) the operation is applicable not only in exstrophy of the bladder, but to other pathologic changes of these organs. [G.B.W.]

Practical Therapeutics.

Under the charge of

A. A. STEVENS, A.M., M.D.

For Perspiration of the Feet.—A case of excessive perspiration of the feet, of years' duration, and of such an offensive character that the subject had contemplated suicide, was cured (*Gazette Med. de Picardie*) by Legoux in 15 days. The means employed were: The feet were first bathed for several days in a weak infusion of walnut-leaves, and then there was applied twice a day a mixture of

Glycerin	10 grams.
Perchlorid of iron	30 grams.
Essence of bergamot	20 drops.

Mix and apply as directed twice each day.

The results are surprisingly rapid and happy.—*Dietetic and Hygienic Gazette*.

Hemoptysis in Pulmonary Tuberculosis.—Hecht (*Therap. Monatshefte*, October, 1900) believes that quinin is the most valuable drug. He is skeptical as to the value of ergot, though he often prescribes it. He has had excellent results with Huchard's hemostatic pills, the formula of which is as follows:

R.—Ergotin	} of each 30 grains.
Quinin sulfate	
Powdered digitals	
Extract of hyoscyamus	

Divide into 20 pills. Five to ten pills daily.

The Treatment of Blepharitis.—Pyle (*International Medical Magazine*, October, 1900) states that in approaching the treatment of blepharitis especial attention should be directed to the causal conditions. Too great stress cannot be laid on the importance of careful refraction under cycloplegia and the prescription of spherocylindric lenses, even of low power, in these cases. Any disturbance of the oculomotor apparatus should be remedied. If, as is the rule, chronic conjunctivitis coexists, a mild stimulating astringent incorporated in a boric acid collyrium should be used. A favorite eye-lotion with the author is the following:

R.—Boric acid	40 grains.
Sodium chlorid	10 grains.
Zinc chlorid	2 grains.
Distilled water	4 ounces.

Stain with pyoktanin and doubly filter after straining.

A few drops of this solution are instilled in each eye three times a day. All scales and crusts should be carefully removed morning and night. Absorbent cotton moistened with warm water, warm boric acid solution, or warm bichlorid solution, 1 to 5000, may be used to loosen the accumulated secretions. Any underlying ulcers should be cleansed, the cilia epilated, and the cavities painted with a 2% solution of silver nitrate or lightly touched with a sharp-pointed lunar caustic pencil. The application of fatty substances facilitates removal of crusts, prevents further occlusion of the glands, softens the skin, prevents excoriation by the tears, and affords a vehicle for local medication. The author prefers as an ointment "Pagenstecher's yellow salve."

R.—Yellow mercuric oxid (amorphous)	1 grain.
Vaseline	3 grains.

Mix thoroughly and put in a collapsible tube. Rub in thoroughly a piece the size of match head, each morning and night.

Scales, crusts, dried secretions, etc., must be thoroughly removed before each application of the salve.

Treatment of Aneurysm of the Aorta.—In the Section of Therapeutics at the recent International Congress of Medicine, Golubinin (*British Medical Journal*, October 13, 19), of Moscow, said he had employed in 8 cases the method of treating aortic aneurysms by injection of gelatinized serum recommended by Lancereaux and Paulesco. The number of injections varied according to the case from 2 to 15. Of the

8 patients 4 died in a short time and the other 4 were lost sight of; in 3 of the cases belonging to the latter group the injections produced no effect. In the remaining one they were followed by slight improvement in the subjective symptoms without modification of the objective signs. Dr. Golubinin had come to the conclusion that the method did not fulfil the expectations that had been founded on it. Dr. Huchard said: In the treatment of aortic aneurysms it is a mistake to allow oneself to be hypnotized by the changes to be brought about in the contents of the sac, that is to say, in the blood, and to take no account of the containing structure. The method of gelatinized injections, which is useful, although insufficient, is open to this criticism. To complete its action, especially in persons with large heart and increased arterial tension—they are almost always at the same time subjects of Bright's disease—medicaments should be chosen which diminish arterial tension, such as potassium iodid, trinitrine, nitrite of amyl, and especially tetranitrate of erythrol, or tetranitrol, which Dr. Huchard has now used for a considerable time and which, as compared with trinitrine, has the advantage of a more durable action. Moreover, an essential point is to supervise to diet, not in regard to quantity, as in Valsalva's method, but in regard to quality. Meat, which holds too large a place in our food, contains toxins, which have an excessively powerful vaso-constrictor action. The best treatment of aortic aneurysm is still absolute milk diet regularly adhered to.

Herpes Zoster.—Lush (*Post-Graduate*) recommends light touches with the actual cautery over the angle of the rib and spine at the exit of the nerve, and the following application:

R.—Ichthyol	2 drams.
Magnesium carbonate	2 drams.
Zinc oxid	2 drams.
Water	4 ounces.

To be sopped on, after which a binder is to be applied to prevent friction. Cannabis indica and arsenic internally are sometimes useful.

Iodized Starch as a Therapeutic Agent.—Solomon (*Merck's Archives*, December, 1900) states that iodized starch may be prepared as follows: 5 parts of iodine are triturated in a small quantity of water, and 95 parts of starch slowly added and carefully rubbed until the mixture is regularly and uniformly a blue black. This is now to be slowly dried, at a temperature not higher than 104° F., and carefully rubbed until a fine, blue powder results. Prepared thus, we have approximately a 5% iodized starch, which is insoluble in water, has the characteristic iodine taste—provided it be held in the mouth a few seconds—and a slight iodine odor. It should be kept in glass-stoppered vials. It may be prescribed whenever iodine is indicated, and when the iodide would ordinarily be employed, iodized starch may be exhibited; its action is prompt, and, in proper dose, energetic. Being an important article of food, starch makes an admirable diluent or menstruum, differing from other bases, like potassium, sodium, strontium, etc., which are each, to a greater or less extent, foreign to human economy. As a rule, from 3 to 10 grains in capsule, pill, powder, or tablet, were necessary to procure a desired effect. Where large doses of the iodide had been attempted, but on account of irritation could not be continued, comparative tests showed the necessity for equally large quantities of iodized starch, as much as 1 to 2 drams, suspended in barley-water, being sometimes given. Even such heroic doses give rise to no distressing local effects on the stomach or bowel mucosa. The advantages of iodized starch may be thus summarized: Physiologically it is an active preparation of iodine, for internal as well as for external use, free from the irritant and caustic action of most iodine products. It is not objectionable to any of the special senses, and its convenience for preparing and administering in capsule, tablet, etc., adds considerably to its virtues. It is sufficiently stable to be preserved almost indefinitely under precautions known to the apothecary. There can be no doubting the absorbability of the iodine in iodized starch, but the iodide of potassium will be found a more active preparation. It is in the cases in which the latter salt or other iodide cannot be tolerated that iodized starch becomes a valuable addition to our armamentarium.

Thyroid Extract in Insanity.—Easterbrook (*Scottish Medical and Surgical Journal*, December, 1900) reports the following results: Out of 130 patients treated, 12 recovered, 29 were improved, and 89 unimproved. Twelve recoveries out of 130 cases is just over 9%. If, however, the obviously incurable cases be eliminated, namely, the 30 "congenital" and "chronic" cases, there remain 100 cases with 12 recoveries, or 12% of recoveries for all cases of insanity which were not hopeless, but were found to be intractable by ordinary methods. His experience indicates that the thyroid treatment of insanity is more efficacious in women than in men, and that the best all-round results are obtained in the insanities connected with child-bearing. His results may thus, perhaps, indicate that the thyroid gland is functionally more active in women than in men. Anatomists and physiologists inform us that the gland is somewhat larger in women than in men, and that it often enlarges during menstruation and pregnancy. He has come across no rational explanation of this physiological enlargement of the thyroid during menstruation and pregnancy, but would suggest that it is either a provision of nature to supply more thyroid secretion for the development of the embryonic tissues in their earliest stages; or more probably, that it is an expression of an increased maternal metabolism, affecting more particularly the uterus and also, in cases of pregnancy, the mammae. All the recoveries were test cases in the sense that previous treatment had been well tried, but had failed. Large doses of thyroid were used in every case of recovery. He has had no case of recovery (except the myxedematous patient) with small or moderate doses. This seems to indicate that it is the briskness and intensity of the metabolic reaction produced which is the valuable effect of thyroid in large doses in insanity, and he is inclined to think, from the clinical type of case which is most commonly benefited by thyroid, as well as from the condition of the urine during thyroidism, that the drug owes much of its value to its power of clearing out of the system various transition and probably toxic products of metabolism.

Operative Treatment of Cirrhosis of the Liver.—Friedrich Friedmann, in the *Centralblatt für die Grenzgebiete der Medizin und Chirurgie* of August 8, 1900 (*Medicine*, October, 1900), has a résumé of the recent literature of this operation. The first case in which there was a deliberate attempt to reestablish the circulation in the abdomen in a case of contracted liver was made in the Royal Hospital of Newcastle by Drummond and Morrison in August, 1894. The authors had been led to perform the operation from a case which had been observed postmortem, in which anastomosis had formed in such a way as to permit of the circulation being carried on without the blood passing through the liver. The possibilities of such communication are said to be several—namely, anastomosis between the coronary veins and those of the lower portion of the esophagus; between the hemorrhoidal veins and the hypogastric veins; a communication between the veins found in the hepatic ligament and those of Glisson's capsule; the veins of the cecum and colon are said to anastomose with the internal mammary vein. Since the first operation, 13 have been performed. Of these, 5 have recovered, 2 were improved, in 1 there was no change, and 5 died. These results point conclusively to the value of the operation, as these patients had very little to look forward to without surgical intervention. The kind of cases in which the operation is indicated are those in which there is a distinct mechanical hindrance in the portal circulation with recurring ascites. It is in this class of cases that so little is to be hoped for from operative measures, the patients having little to look forward to except a lingering illness and comparatively early death. The technic, as carried out in most of the cases, is comparatively simple, consisting of a small incision into the abdominal cavity, through which a careful exploration is made of the liver, gallbladder, and the surrounding parts. The peritoneum is curetted over the anterior surface of the abdomen, and the great omentum is attached by sutures to the abdominal wall. The peritoneum has its epithelial covering removed over the lateral and anterior portion on the left side of the abdomen, to which the spleen is likewise attached. A glass drain is then inserted, and all ascitic fluid of the abdominal cavity is removed. This drainage is continued until no further fluid is formed, which shows that the collateral circulation has been estab-

lished. The success of the operation is absolutely dependent upon a functional intact condition of the liver cells; the ascites being merely dependent upon mechanical hindrance to the onward flow of blood. Hence, in cases of cirrhosis it should be undertaken before the process in the liver has advanced so far as to involve the functional integrity of these cells.

Indications for Bleeding.—In the *Congress of Medicine*, 1900, Hayem (*Treatment*, November 1900) recommended this procedure under the following conditions:

A therapeutic measure is "indicated" when it is established that it brings about under given circumstances an amelioration more marked than any other means can procure.

The procedure of bleeding cannot then be considered as "indicated" save in those cases in which it acts with an incontestable superiority over all other therapeutic measures.

The "antiphlogistic method" of repeated bleedings appears to be definitely condemned.

The opening of a vein on one or several occasions, at relatively long intervals, deserves to be maintained as a useful and effective measure.

The cases in which bleeding is indicated are, speaking generally, those in which life is immediately endangered, either by circulatory arrangement or by toxemia, in such conditions as the following:

1. Acute edema of the lung, particularly in disease of the large vessels or of the kidneys.
2. Certain cases of pneumonia of edematous or simply congestive type.
3. Certain mechanical troubles of the circulation, due to disease of the heart or great vessels, particularly in high arterial tension, but also in some cases of evident asystole, congestive, and hemorrhage in subjects of high arterial tension.
4. Recent or acute uremia; puerperal eclampsia; intoxication of the blood by certain gases, notably carbonic oxid.

Value of Ovarian Organotherapy.—Krusen (*International Medical Magazine*, November, 1900) draws the following conclusion from 3½ years' experience with ovarian extract in selected cases: 1. The employment of ovarian extract is practically harmless; no outward effects beyond slight nausea have been noted, even when full doses have been administered. 2. In the treatment of amenorrhea and dysmenorrhea, no good results were secured; (although in some cases of the amenorrhea of obesity remarkable results have been attained by the use of the thyroid extract). 3. The best results were seen in the second class of cases for the relief of symptoms of artificial menopause, where in a few instances the congestive and nervous symptoms were apparently ameliorated. 4. No appreciable result was noticed in the use of ovarine in the natural menopause. 5. No definite or exact reliance can be placed upon the drug, as it often proves absolutely valueless where most positively indicated. 6. It is extremely problematic whether, in those cases in which relief was noted, the effect was not due to mental suggestion rather than to any direct physiologic action of the drug. The neurotic type of individual demanding this treatment will often be relieved by any simple remedy. 7. In those instances in which effects were noted, increase in dosage seemed to have little influence in maintaining the effect or preventing the patient becoming accustomed to its use. 8. In conclusion, the theory which suggests the use of this extract seems to be at fault, and the administration of ovarine or ovarian extract, is based upon a wrong assumption as to the function of the ovary. In organotherapy, the best results have been attained by the use of thyroid and adrenal glands, and the ovary in function is in no sense analogous to these organs. Its principal function is ovulation, and if any peculiar product is coincidentally manufactured, the isolation of this product has not yet been accomplished.

Fleischig's Opium Treatment of Epilepsy.—Séglar and Heitz (*Archives de Neurologie*, August, 1900) report the results of Fleischig's treatment in two series of cases of epilepsy. In the first series of 12 cases, 6 were able to undergo the full treatment without any serious toxic results; in 3 of these the treatment had no result, while in the other 3, watched for a year, the number of convulsive attacks was reduced by about one half. In the second series of 10 cases, the administration of the opium caused toxic symptoms in all cases, so that the treatment was not continued.

A PHYSICIAN'S HOLIDAY AT KARLSBAD.

By JAMES TYSON, M.D.,

of Philadelphia.

Professor of the Theory and Practice of Medicine in the University of Penna.

To THE American seeking Karlsbad, by far the most convenient route is by steamer to Hamburg and thence by rail via Berlin and Dresden, arriving in 18 hours by day or night train. A break in the journey may be made at either of the last named places. Northern Germany in somewhat flat and monotonous, but to one who travels it for the first time it is still sufficiently novel to make a day trip enjoyable. Dresden once passed, the scenery becomes more varied and attractive. First is traversed the valley of the Elbe, swiftly flowing between high and sometimes rugged hills, then the valley of the Eger to its junction with the Tepel on both sides of which Karlsbad is built. Some minutes before arriving at our destination its nearness is proclaimed by a fine view of the Stephanie Tower, erected on the summit of one of the many adjacent hills to commemorate a visit of the Princess Stephanie. Insignificant as appears the little river Tepel, to the visitor in the season, on more than one occasion freshets have washed away its bridges, while the town itself has suffered destructive inundations. So narrow is the valley in places that there is room for but a single row of houses and shops on each side. Much of the town is built in terrace-like arrangement on the mountain sides. It has grown rapidly of late years and accommodates now 15,000 permanent residents and 50,000 patients annually, exclusive of visitors and tourists. Itself over 1200 feet above the level of the Adriatic Sea, the town is further surrounded by the Karlsbad Hills, which rise from 200 to 800 feet higher. As the stream is ascended the hills separate to form a wide, luxuriant meadowed valley. This valley opens to the north, which explains the lower and changing temperature that characterizes it as contrasted with the adjacent country, and necessitates at all seasons a judicious selection of clothing. The hills are also covered with a dense growth of fir, pine, oak, and beech, which by their various shades of green add a further charm to the beautiful scenery. The hills are traversed by miles and miles of paths of easy grade provided and scrupulously cared for by the authorities for the pleasure and benefit of the patients.

It is at first a disappointment to the visitor to find that the springs are not in the center of beautiful parks, as is the case at so many of the European spas, but are in the heart of the town. In this respect it is more like Aix-la-Chapelle. The springs are, however, surrounded by imposing colonnades and halls erected for the convenience of visitors, while the missing park is more than compensated for by the walks referred to, almost every one of which leads to a picturesquely situated café, offering tempting refreshment to the pedestrian, and commonly presenting an extended view of the surrounding country.

The several springs which constitute the Karlsbad Spa do not differ essentially in the composition of their waters, the chief difference being in the temperature at which they emerge from the earth. Sodium sulfate, sodium carbonate, and sodium chlorid are the principal constituents of each, and are found in astonishingly close proportions in the different springs, as seen in the appended table:

Thus the springs are of the alkaline saline class, containing also considerable carbonic acid. The temperature of the different waters as they are discharged is as follows:

	DEG. R.	DEG. C.	DEG. F.
Sprudel.....	58.0	72.5	162.5
Franz-Josephs Quelle	51.0	63.7	146.7
Bernhardsbrunn.....	48.5	60.7	141.2
Felsenquelle	47.8	59.7	139.5
Neubrunn.....	47.2	59.0	138.2
Theresienbrunn.....	46.2	57.7	135.8
Schlossbrunn	39.2	49.0	120.2
Kaiserbrunn.....	38.8	48.5	119.3
Muehlbrunn.....	38.4	48.0	118.4
Russische Krone.....	36.4	45.5	113.9
Marktbrunn	32.8	41.0	105.8

	DEG. R.	DEG. C.	DEG. F.
Elisabethquelle	32.5	40.7	105.2
Parkquelle	32.2	40.2	104.4
Kaiser Karl Quelle	31.5	39.4	102.9
Kochberger Quelle.....	31.5	39.4	102.9
Spitalbrunnen.....	28.2	35.2	95.3

It will be seen that the water from the Sprudel Spring is the warmest, being 162.5° F. It is also spoken of as the "strongest," but it is evident that any increased activity cannot be due to increased proportion of constituents. It is probably due to the higher temperature, which favors its more rapid absorption and greater activity. It is certainly the most interesting to the casual visitor. Often totally obscured by the steam which arises in dense clouds above and around it, it suggests a huge boiling caldron. From its center spout columns of hot water which scatter the spray so widely that the water must be dipped up with cups at the end of long poles, while the girls serving it are protected with waterproof coats and jaunty rubber caps.

All the springs belong to the municipality of Karlsbad, and immense sums of money have been spent from time to time in constructing handsome colonnades and sumptuous bath-houses about them. Of the former, the finest is the Mühlbrunn Colonnade, erected at a cost of \$320,000, competing in architectural beauty with any similar structure in the world. The Sprudel Pavilion, built over the Sprudel and Hygeia Springs, is a large and handsome hall constructed of glass and iron. In connection with it are also bathhouses. The bathing establishments are the "Kurhaus," with mineral water-baths, mud baths, douches, common water baths, and carbonated water baths; the "Neubad," with Sprudel water baths and mud baths; and latest of all, the costly "Kaiserbad," completed in 1895 at a cost of nearly half a million dollars. It contains thermal and common water baths, cold douche and shower baths, mud baths, electric baths, and electric-light baths, with a complete Zander's establishment for Swedish hygienic gymnastic and massage. These fine modern buildings, some of which contain also offices and reading-rooms, were constructed in rapid succession since 1875 to meet the growing demand of annually increasing visitors, taking the place of older and more imperfect structures.

Why patients go to Karlsbad.—It is creditable to the physicians and others interested in Karlsbad, that they do not claim that the "Cure," as it is called, is applicable to all diseases. On the other hand, they publish a long list of which the contrary is stated. Thus it is contraindicated in inflammatory and febrile affections, in bronchitis and tuberculosis of the lungs, in secondary and tertiary syphilis, in carcinoma and the various degenerations, in diseases of the heart and bloodvessels, especially atheroma and aneurysm, in pregnancy, in advanced Bright's disease, in the debility of old age, or where there is decided weakness from any cause; nor, so far as I know, is any efficiency claimed for these waters in the treatment of diseases of the nervous system. Cirrhosis of the liver is also an affection for which no benefit is claimed.

Before taking up the diseases for which the treatment is beneficial, let us consider first the effect of the waters, and in what the treatment consists. As to whether they are palatable or not, is largely a matter of individual taste. To me both warm and cold waters were agreeable, and to the majority they are not unpleasant. Yet, during my visit, I met one of my Philadelphia medical friends who told me that the Sprudel water so nauseated him that he was unable to take it. This I believe to be unusual. When drunk they come first, of course, in contact with the mucous membrane of the stomach and bowels, and are said to be soothing to these surfaces, allaying pain and arresting spasm. These effects may be produced by neutralizing unnatural acidity, I see not how else. After absorption, their alkaline constituents increase the alkalinity of the blood, promote its solvent power and its mobility. Thus is counteracted any tendency to stagnation, especially in the portal circulation. This effect is further favored by the purgation which is induced in a few days, if not immediately after their use is commenced. Such facility of circulation also relieves the lymphatic vessels, and it is thought favors molecular change and the absorption of subcutaneous fat and inflammatory products. By the purgative effect, too, the bowels are flushed and cleared of mucus and accumulated feces, while normal secretion is thus stimulated.

The effect of the waters is increased when drunk on an empty stomach, when absorption is most rapid. The hotter waters are taken when more energetic action is desired, the cooler when a less positive effect is sought. The greater activity of the hotter waters is ascribed, as already stated, to their more rapid absorption. The quantity advised varies from two to six cups a day—10 to 30 ounces—and is determined by the physician who is consulted. So far as I could ascertain, the larger quantities are rarely ordered. Several minutes should be occupied in the drinking, and from 10 to 15 minutes allowed "between cups." The promenade, the music of the orchestras which play from 6 to 8 at the more popular springs—the Mühlerunn and the Sprudel—the novel surroundings which include especially peculiarities of appearance and dress characteristic of different nationalities, all contribute to make the time pass pleasantly and rapidly.

But the drinking of the waters is by no means all of the Karlsbad treatment, and it is conceded by the most enthusiastic of its supporters that if limited to this only, the treatment would be far less efficient, as well as less picturesque and pleasurable. The visit to the springs is early, between 6 and 8. Perhaps the largest number is found about 7 o'clock. After the allotted number of glasses has been drunk the patient proceeds to one of the numerous bakeries and buys the bread for his breakfast, bread the most delicious to be found. It may be a prescribed quantity in the shape of rolls, or crescents, or zwieback, or the quantity and variety may be limited only by the appetite and taste. Then he proceeds to the meat shop, where he buys his ten to twenty kreutzers worth of tempting cold boiled ham. The pink and white paper packages containing these are carried to one of the numerous cafes from half a mile to two miles distant. A table is selected always in the open air, if weather and season permit, whence, too, there is commonly a pretty outlook towards the rich green meadows and hillsides. By this time our patient is quite hungry and welcomes one of the neatly dressed waitresses who comes with a cheerful "Guten Morgen," for his order for eggs and coffee. The coffee is scarcely less excellent than the bread, and he is soon busy in the pleasurable occupation of breakfasting. So far as my observation went, this breakfast is not at all limited as to quantity, and the delightful surrounding and abundant leisure do not dispose one to eat less than he desires.

Breakfast over, there is more walking. It may be for a short distance or for miles on the many pleasant paths already described, where abundant resting places are provided, until noon is near—the hour at which the baths are usually taken, although many are prescribed for early morning hours. For it is only on the physician's prescription as to kind, duration and temperature that the baths are allowed, unless the visitor happens to be "selbst ein Arzt," when not only is he permitted to select his own baths, but also becomes the guest of the town, receiving a card which admits him to the baths free of cost, except, of course, the *douceur* to the attendant. In common with all others who remain more than a week, he must pay the music tax, which is collected by a polite official who comes direct to his rooms without ceremony. The tax is five florins, or \$2.00, for the ordinary well-to-do visitor who is termed a person of the "first class," eight florins, \$3.20, for a party of two persons, with a further reduction *per capita* for parties of large numbers.

The bath completed, dinner follows shortly. For this the neighborhood of one o'clock is advised, the late dinner hour being discouraged by the physicians. The dinner may also be more or less prescribed by the physician whom the patient has consulted, but here again, there is much erroneous conception as to what constitutes the Karlsbad diet, doubtless because years ago greater stringency was insisted upon than at present. At the present day at least the rigid dietary rules which if neglected are followed by severe punishment are a myth. For the patient under treatment the food is simple but sufficient. It may include soup, fish except salmon, beef, mutton, poultry, game without rich dressings, green vegetables, including peas, beans, spinach, cauliflower and the like. Spices and stimulating condiments, such as pepper and mustard, are prohibited. Soup is often disallowed because it occasions distention. Nor is wine always prohibited. In fact, it is sometimes ordered by the physician, especially the light wines of the country, which are good and inexpensive. So, too, the delicious Münchener

or Pilsen beer is sometimes allowed and even prescribed. On the other hand, champagnes and heavy wines are rightly prohibited. The town water of Karlsbad is pure and wholesome, though it is quite usual to drink some one of the "sauerbrunn," or natural carbonated waters, in which the vicinity abounds, especially the Giesbübler and Bliner which are also used in admixture with wines. On the other hand, waters highly charged with carbonic acid such as Apollinaris are discouraged because they are thought to distend the stomach by liberated gases. Dinner over, a short stroll followed after a brief rest by a longer walk or a drive may be taken. At four o'clock the music again invites to the garden's and café's air. Supper, especially, should be kept within bounds. Tea, bread and butter, an omelet and a little stewed fruit constitute it for the most part. In the evening for those who desire it is the opera in one of the most attractive little opera houses on the Continent, and at some of the larger hotels, like Pupp's, there is music, but by 10 o'clock most persons are in bed or at home, so that a marvelous quiet settles down on the town. Indeed nothing so much impressed as the absolute stillness which pervaded the town soon after 10 o'clock. Streets which during the entire day, and especially in the early morning and early evening, are filled with pedestrians are deserted and "early to bed" is as invariable as "early to rise" for which it is also a preparation. On the whole, the life at Karlsbad is an ideal one, with just sufficient amusement, exercise, and treatment to occupy the time pleasantly, so that it is not surprising that persons return year after year for the pleasure as well as the health-giving advantages afforded.

As to the diseases for the treatment of which Karlsbad is famous, gout and its complications are foremost. The rationale of the effect can only be inferred, but it appears reasonable to believe that the action of the waters is in the first place, depurative and neutralizing on the *materies morbi*, be it retained uric acid or something else—depurative by their aperient action, and neutralizing through the increased alkalinity of the blood resulting from their absorption. Second, the baths further increase elimination, and in conjunction with massage, tend to remove the local swellings and stiffness of joints which are responsible for so much discomfort in gout. Third, the vigorous exercise which forms an important part of the treatment still further increases elimination and contributes to the removal of the conditions referred to. Fourth, the restricted diet from which proteids and wines are excluded or reduced to a minimum, keeps out substances which go to make up the toxic product causing the disease. It is probably the combined action of these agencies which is responsible for the beneficial effect of the Karlsbad treatment on the symptoms of gout. It is said in some instances the pains of gout are increased by the first effect of the waters which dissolve out the uric acid from other situations and carry it to other vulnerable points, whence it is ultimately washed out. It is more than likely that the beneficial effect of the treatment on gout would be prolonged after the patient returns to his home if the same line—hygienic and dietetic—were kept up. It is not only the appetite and careless eating and drinking that are responsible for the retrogression, but also the trouble and difficulty of carrying out at home other parts of the treatment, which cause it to be gradually relaxed and followed by relapses which make recurring visits necessary. To be surrounded by social and business demands at home is very different from being one thousand or more miles away with nothing to do but to carry out a treatment for which expressly the journey is made.

All that has been said of gout is equally true of the tendency to uric-acid deposits and gravel, the solution of these being favored by the alkalinity of the blood and secretions.

The more usual forms of rheumatism of other than gouty origin, articular and muscular, are also successfully treated at Karlsbad by massage, exercise, the thermal baths, and especially the peat baths, which are a unique experience. Unpleasant as is at first the idea of submerging one's self in a mass of thick hot mud, yet the first unpleasantness overcome, the experience becomes a pleasant one. The usual notion of mud as something purely filthy is soon dispelled, while there is a fragrance about the organic matter of the peat which is agreeable. It is brought from some distance in the vicinity of Marienbad where the Karlsbad authorities own a tract of peat land. The peat is ground to a required degree

of fineness and then mixed with the hot Sprudel water. The bath is taken commonly at a temperature of about 28° Reaumur, or 95° Fahrenheit. Massage forms an important part of the treatment of rheumatism.

While upon the subject of baths I may as well describe the two remaining baths which seem worth special allusion. They are the electric water bath, the electric-light bath and the carbonic-acid water bath. In the electric water bath the patient is immersed in the ordinary tub bath at a temperature of about 95° F., and becomes a part of the electric circuit. With sufficient strength a tingling burning sensation over the entire surface of the body which with stronger currents becomes even painful. In a short time the skin becomes decidedly reddened. I do not know that any settled explanations of the operation of the electric water bath is proposed by those who employ it honestly for other than the mental effect. As stated the only evident effect is on the skin. It is undoubtedly counterirritating to the skin. Through this nutrition may be influenced first in the skin itself and second upon the muscular and nervous tissues below it. I think it not unlikely that this form of bath may act as a cardiac stimulus similar to that of the Nauheim bath.

The electric-light bath is an interesting bath. It consists of a cabinet in which the patient is enclosed, except his head. Numerous electric lights project from the sides of the cabinet towards its interior. The bath is a sweat bath in which the heat is derived from the electric lights, and of which the chief feature is that the sweating takes place at a much lower temperature than in a vapor or hot air-bath. My recollection is that it is about 95° F. None of the physicians with whom I conversed at the Kaiserbad were able to offer any explanations.

For the carbonic-acid bath, the sprudel spring water is charged with carbonic acid under pressure, and the baths seemed to me almost identical with the baths at Nauheim which I also visited. The little bubbles of carbonic acid collect in immense numbers on the skin precisely as in the Nauheim baths, and as the water is also a strong saline solution, the same effect of cardiac stimulation may be reasonably expected.

Next after gout—if not before—come portal congestions and gastrointestinal catarrhs. They are influenced through the depurative action of the waters, the bathing, massage, exercise, and restricted diet. Careful adjustment of diet is most important in these affections and the local physicians look closely to this, and with the happiest results.

Gallstones and hepatic colic are among affections for which much is claimed by the Karlsbad physicians, and apparently with reason. It is held that the expulsion of stones is facilitated, sometimes painlessly, but more frequently with the colicky pain usually associated with such expulsion after the thermal treatment. This seems to be generally conceded. An incontrovertible explanation has not been offered. The most likely is that the results depend upon a flushing of the gallducts by a thin bile and the free purgation which drains especially the duodenal end of the bowel. Another very interesting consequence of the reputation Karlsbad possesses in this respect is the aggregation of a large number of cases of gallstone impactions, which failing of relief by the effect of the waters come to the surgeon's hands. As a consequence many cases are received into the local hospital by Dr. —, local surgeon, who has had remarkable success.

Diabetes is another one of the ills for which Karlsbad is resorted to by large numbers. It has seemed to me that the effects are among the least satisfactory of any claimed. This conclusion is not based on observation while at Karlsbad, for I was there too short a time to justify any conclusions. But it has happened to me to send a great many diabetics to Karlsbad, and while many have been benefited, these have always been the milder cases, while the improvement has not seemed more permanent than which always took place when they first came under treatment at home and abroad, and especially abroad where the cooperation of other favorable influences is brought to bear. Indeed, the most claimed by Karlsbad physicians with whom I have discussed the matter, seemed to be as follows: In cases coming to Karlsbad where the best that could be done at home was to reduce the percentage of sugar to a fraction of 1%, the result of treatment at the Spa is to take the sugar out altogether. In cases where the home treatment removed

a portion of the sugar, but left a considerable percentage, the Karlsbad treatment reduced the percentage of glucose, but could not eliminate it altogether. This increment of effect may be the direct effect of the water drunk, probably through its alkalinity. An experiment by Salkowski, to which my attention was called by Dr. Edgar Gans, at Karlsbad, tends to confirm this probability. He noted first that the artificial digestion of starch by pancreatic extract was delayed by the addition of saccharine, and second that this inhibitory effect was counteracted by the addition of sodium bicarbonate and the digestion proceeded. On the other hand, the dietetic treatment is no less rigid than at home, commonly more so, and more strictly carried out, while the cheerful surroundings have their due influence. There can be no doubt, therefore, that to the diabetic who is not too far advanced in the disease, and who can afford a somewhat expensive journey, a trip to Karlsbad will be of service by diminishing or removing his symptoms, by invigorating and encouraging him, giving him a fresh start as it were, whence the outlook is promising and hopeful.

Obesity is one of the recognized objects of the treatment. Indeed, I never before saw so many fat men and women gathered in one place, though by no means every fat person who goes to Karlsbad goes there to be treated for obesity. The majority are altogether too deliberate in their actions, and they eat too much. The treatment for obesity is undoubtedly effective in reducing fat, but here as elsewhere the effect is only accomplished by hard work. The following experience related by the late Professor Horatio R. Bigelow in his interesting paper on Karlsbad, published 13 years ago, may be considered a sample. He says: "When I came to Karlsbad, I weighed between 186 and 190 pounds (American). As I am only 5 feet 6½ inches tall, this was too portly, even for a London alderman. Dr. Grünberger advised the *Kur*. I began with 2 glasses (March 16) of Marktbrunn daily, to which was added on March 20, 1 glass of Mühlbrunn. This was never increased during the 8 weeks of my cure. The water was sipped gradually; then, after a interval of 15 minutes, the second glass was taken, and so the third. After that a walk of from 1 to 2 hours and then breakfast. A cup of tea or coffee (with milk and sugar), 2 rusks and 2 soft-boiled eggs, then a climb of 2 or 3 hours, and home to dinner—a piece of rare meat and one vegetable with an occasional glass of Hungarian wine. Then another long walk, followed by a supper at 7, consisting of tea rusks, and cold meat. I took a few warm and vapor baths, especially when in Berlin, where I was called upon business, being absent about 10 days. While away I kept up my diet rules most strictly, but not being able to exercise as vigorously, I indulged somewhat in Turkish baths. Latterly, I have given up coffee and take no milk in my tea. At first the waters caused a natural but rather active movement from the bowels; then, for 2 or 3 weeks the discharges were more frequent (twice, and sometimes 3 times per day), and then came an interval of constipation.

"I weigh now (May 26) about 155 pounds with winter flannels. My weight, naked, at the Kur Haus bath-rooms was, on May 23, 87 kilograms—148 American pounds. I exercise 3 or 4 hours daily, and observe a vigorous self-denial in matters of diet. It will be seen that from March 4 to March 10 I lost nearly a pound per diem, but during this time I am sure that I walked between 24 and 25 miles daily. At no time have I felt unpleasantly." He says, moreover, "the share of the waters in this role must be considered a small one."

Be this as it may, I am confident that the benefits of the Karlsbad treatment are very great to fat persons, even if it does not reduce their fat, or reduces it moderately, as is more often the case. It is the fat person whose circulation is sluggish, whose bile is thick, whose gallbladder is full of faceted stones, with or without biliary colic. All of these conditions are benefited by the "cure."

The Karlsbad waters are claimed to be efficient in certain diseases of the skin. Erysipelas migrans, sclerosis of the skin, urticaria, pemphigus, and eczema in their milder forms, and furunculosis are mentioned. I did not have an opportunity to see any of these affections under treatment while at Karlsbad, but I have seen a most obstinate case of urticaria which resisted all other treatment at home, greatly relieved by full doses of the Karlsbad Sprudel salt, dissolved in hot water. At the end of 1 week's treatment a life of comparative comfort was substituted for one of misery.

A most important and comparatively recent application of

the Karlsbad mineral waters has yet to be described. It is that of Dr. J. Müller, an accomplished specialist in nose, ear and throat affections. He avails himself of the hot Sprudel water in spraying the nose and throat with powerful sprays produced by the pressure of expanding compressed carbonic-acid gas. By substituting carbonic-acid pressure for atmospheric air pressure he reduces the pressure from 7 atmospheres to $1\frac{1}{2}$ atmospheres. The spray is allowed to pass for 10 to 15 minutes into each nostril and 10 to 15 minutes into the throat. In this way a most effectual irrigation of these parts is secured as compared with which the ordinary nasal spray is as mist compared with rain. This treatment is applied for nose, throat and laryngeal affections, and I have reasons to believe that it is efficient. When in Vienna, where Dr. Müller practises in winter, he uses the Karlsbad Sprudel salt dissolved in hot water.

No description of Karlsbad and its treatment at this day should omit an allusion to the finely appointed Zander establishment for Swedish hygienic gymnastics and massage at the new "Kaiserbad" under the direction of the accomplished Dr. D. Tynauer. This probably surpasses all similar institutions of the kind, being the newest and latest. It is very interesting to watch the patients passing from one machine to another, and securing thus every conceivable variety of gymnastic exercise, everything working smoothly and spiritedly. I will conclude this paper by quoting without comment the purposes of the treatment.

1. To prevent the injurious consequences of a sedentary mode of living or of one-sided muscular action.

2. Ailments and disorders of the organs of movement, as: sprains, stiffness and weakness after fractures of bones and other injuries, crookedness of the limbs and of the vertebral column.

3. Dilations of the stomach and bowels, chronic constipation, enlargement of the liver, hemorrhoids, neuralgia (sciatica), writer's-cramp and similar affections, chorea, cases of paralysis and weakness of various kinds.

4. Obstructions to the circulation of the blood, diseases of the heart and their attendant consequences, overaction of the heart, weakness of the heart, beginning fatty degeneration of the heart, changes in the bloodvessels from old age, nervous heart complaints.

5. Diabetes mellitus, uric-acid diathesis, gout, adiposity and chronic metal-poisoning.

"In all these cases, says the published statement," a combination of the Karlsbad course of baths and waters with the mechanical treatment will be in the highest degree successful."

The Most Suitable Time for Visiting.—Karlsbad may be visited at any time, but what is known as "the season" begins with the fifteenth of April and extends to the first of October. The most popular months are June and July, and during these two months the wealthiest and most fashionable visitors are found, while the rates for rooms are higher. August is also a popular month, but towards the end of it there is quite a decided falling off in the number of patients and visitors. To a person having full control of his time, I should say complete your "Cure" by the middle of August, for although there are many lovely days after this date, the mornings and evenings become cool and the latter damp, especially in the deeper and narrower parts of the valley where the air cannot change rapidly and thoroughly, and persons subject to catarrhal troubles are apt to take cold. Moreover, although Karlsbad is an exceptionally salubrious city, in which no epidemic has ever prevailed, it is reasonable to suppose that the coming and going of 50,000 visitors must have an effect towards the end of the season in contaminating the purity of the air and drainage, while occasionally a case of typhoid fever does crop out towards the end of the season.

The Committee on Scientific Research of the American Medical Association desires to announce that it has available the sum of \$500 for the assistance of researches to be undertaken in the next 6 months, and that the money will be appropriated if applications be received within the month of January, 1901. Applicants should state clearly the character of the research to be undertaken, and the facilities at their command, addressing Dr. H. C. Wood, chairman, 1925 Chestnut St., Philadelphia, Pa.

PRIMARY BRANCHIOGENIC CARCINOMA.¹

By FREDERICK SHIMANCK, M.D.,

of Milwaukee, Wis.

THE following case, although rare, may prove interesting if not instructive. The very fact of infrequency makes it incumbent upon us to consider it more or less in detail. It is very discouraging indeed to one who possesses an investigating turn of mind to encounter disease which may be never or rarely exhaustively treated by medical authors.

Before we proceed to the description of the case under consideration it may be profitable to briefly set forth the anatomy and embryology of the development of the neck. It is not necessary to enter into a minute exposition of this very interesting subject; I merely desire to point out some of the salient facts in order to bring out more prominently some of the practical sides of embryologic teaching. The branchial arches and clefts are the primordial structures of the neck and face; they enter into the construction of the jaw, hyoid bone, thymus and thyroid glands; styloid process, the stylohyoid ligaments, and assist in the formation of some of the other soft tissues of the neck, etc. With the completion of all of those parts the last vestiges of embryonic structures gradually disappear, with the exception of the first one, from which the external auditory canal, the cavity of the tympanum, and the eustachian tubes are developed. From the difference in the rapidity of growth of some of the arches, various cavities are formed as follows: Sinus cervicalis, fundus præ-cervicalis, fundus branchialis, sinus pyriformis. These are lined with ectodermal or epithelial elements. These enter into the formation of the thymus and thyroid glands, etc. Abnormalities in the development may lead to fistulas, dermoids, cysts, or other tumors, malignant or benign. All of the sinuses and pouches should become obliterated in the formation and development of the hyoid bone, the thymus and thyroid glands, etc. Should nature fail in her physiologic functions we may find enclosed in the depths of the neck epithelial elements which are the prerequisites in the formation of primary carcinoma. The first and second branchial arches and clefts by their more rapid growth overlap the third and fourth, thus forming a space lined with epithelial cells, called cervical sinus; other sinuses are formed in a similar manner.

From this short and superficial review it may be very readily seen why epithelial tissues are at times found in the depths of the neck where nothing of the sort, under natural histologic conditions should ever exist, and the reason for the development of primary epithelioma.

In making differential diagnoses between tumors of the neck it is important to remember that branchial tumors, springing as they do from embryonic remnants of the branchial clefts and arches, are situated always primarily anterior to the sternomastoid muscle, between that muscle and the hyoid bone. The second cleft and arch, which are nearly always concerned in the development of the neoplasm, are situated between that muscle and the hyoid bone, whence the tumor spreads posteriorly, etc., until finally the entire lateral aspect or the neck may become involved. Of course, this is not the only point of importance, but, I think, one of greatest weight. The depth of the tumor,

¹ Read before the Wisconsin State Medical Society, June 2, 1900.

its firm adhesion, more properly speaking, intimate amalgamation, for it forms part and parcel of the bloodvessels and nerves of the neck, are perhaps the most important conditions from a pathologic standpoint.

The case occurred in a male, aged 49, a farmer. Up to 5 years ago the history showed perfectly health; the family history was negative. Then a tumor developed in the right half of the lower lip, which became indurated, and eventually ulcerated, destroying a considerable part of the lip.

Diagnosis of epithelioma was made, and excision of the ulcerated and indurated mass followed. The union was good and the result all that could be desired, *i. e.*, no recurrence in the scar up to the present time, or nearly 5 years; but 1 year subsequent to the operation an enlarged gland of about the size of a hazel nut was found situated over the right submaxillary gland, painless and movable. No other glands were at that time, or at any other time, discovered. The physician who had the patient in charge considered it carcinomatous and removed it. No microscopic examination, to my knowledge, having been made, it is impossible to state what its construction was; but, judging that it was solitary, freely movable, and absolutely painless after having attained the size of a hazel nut, it is reasonable to conclude that it was not malignant. At the beginning a secondary gland tumor is generally movable because the infectious material is still confined and limited to the glandular parenchyma, the capsule eventually becoming involved and destroyed, when fixation and infiltration of the surroundings rapidly follows.

In the very beginning, then, mobility of a gland tumor is not a feature to be regarded in favor of benignity, but mobility and solitariness of a gland tumor, after having existed some time and having attained considerable size, is, in my opinion, evidence against malignancy.

It is fair to assume that in regional infection involvement of several glands takes place simultaneously or in rapid succession, since many lymphatic vessels are taking up microbes or cells from the ulcerating surface, it is usual, therefore, to find many, or a whole chain of lymph nodes enlarged. Carcinoma being of epithelial origin it never occurs primarily in the glands of the neck.

The conclusion irresistibly points to adenitis, probably of an infectious nature, from the throat or mouth.

In June, 1899, or about 4 years after the glandular episode, the patient presented himself for treatment of a tumor of the right side of the neck. On examination it was found that a round, smooth, and an elastic tumor of about the size of an orange, apparently fluctuating, existed in the right upper triangle of the neck, situated between the hyoid bone and mastoid process, beneath the sternomastoid muscle, of about 2 months' growth. It was insensitive to pressure, nor was it causing any great subjective phenomena, excepting some neuralgic pain, not, however, of sufficient moment to disturb his rest. It appeared to be quite movable, but that must be understood in a relative sense on account of a great looseness and mobility of the tissues of the neck—any tumor there situated will be comparatively movable unless there is great induration from inflammatory or malignant infiltration.

Nothing else could be discovered. At first thought, from the history as given by the patient, diagnosis of malignant tumor was made with, however, considerable reserve, owing to its smoothness, painlessness, and lack of infiltration.

An exploratory incision was made over it parallel to the anterior border of the sternomastoid, and, as this was gradually deepened, suddenly a gush of yellowish transparent

fluid took place, followed by a complete collapse of the tumor.

The interior of the sac was lined with an irregular membrane; the prominences or proliferations apparently consisted of granulation tissue. The whole of the interior was thoroughly curetted, and subsequently painted with iodine.

The diagnosis of carcinoma remained undecided, and further opinion was withheld pending the microscopic examination of the scrapings by Dr. Evans, of Chicago, who pronounced it epithelioma.

After closure of the opening rapid refilling of the cyst took place as also a considerable enlargement of the entire tumor. One month later a second attempt at removal was made at the most urgent solicitation of the patient, however, against my advice and convictions. This operation consisted in freely laying open the field of operation through a large U-shaped incision, which commenced anterior to the sternomastoid below the angle of the jaw, and was continued downward below the tumor, then backward across the neck in a curved direction, thence upward and terminating near the external occipital protuberance.

This incision extended through the skin, the superficial fascia, platy-ma, and the sternomastoid muscle. This large flap was raised from below upward, exposing a very large area which afforded a beautiful view of the entire interior surface of the cyst.

Its walls were composed of a tough membrane of about the thickness of a postal card, on whose surface sprouted, here and there, granulation-like masses, the surrounding tissues, or those tissues being in intimate relationship with the neoplasm appeared to the naked eye and to the touch normal; no enlarged glands were palpable either in the immediate neighborhood of the tumor or elsewhere. An attempt was made to dissect away the cyst wall, but it soon became evident that nothing short of a removal of the entire side of the neck would suffice, and so the operation was discontinued.

As has appeared above from the embryologic considerations that those neoplasms of branchial origin enter, so to speak, into the constitution of the normal histology of the neck, the extent of malignant dissemination in carcinoma is beyond estimation.

I do not see the philosophy of those extensive and hazardous procedures when no hope can be entertained of ultimate recovery, or even of the prolongation of life or of alleviation of suffering.

The growth of the tumor increased very markedly after this attempt, and in about 8 months from that time the patient succumbed to hemorrhage from the tumor. From the situation of the tumor, from its cystic character, with an epitheliomatous degeneration, diagnosis of branchial carcinoma had been made, and probably of primary origin.

From the history of this case this would at first sight seem highly improbable, but if we take into consideration the time—5 years—which had elapsed since the appearance of the lip epithelioma, and secondly, no gland involvement following it which could be regarded with any degree of certainty, it must be admitted that the branchial carcinoma simply developing later than that of the lip does not prove its dependence upon the latter.

Tilman says in speaking of the prognosis of carcinoma:

"We make distinction based upon their mode of origin, between continuous and regional recurrence; the former spring from portions of the primary tumor which were left behind at the time of operation, while the latter (regional appearance) are looked upon as independent new tumors in the cicatrix or its vicinity. The second kind sometimes make their appearance only after the lapse of years."

All recurrences which occur later than 2 years after operation should be considered, according to Snow, "new independent tumors resulting from new injurious agencies." In looking up the literature one is struck with almost the entire absence of anything definite

upon the subject. Jordan¹ of Heidelberg, in Bergman's, Bruns', and Mikulicz's Surgery, which is now being published, contributes a very interesting and practical article from which I have translated as follows :

Deep carcinomas of the neck are generally situated in the upper triangle, and fully correspond in construction with those of the skin. There being, normally, no epithelial tissue in the place of their occurrence, Volkman, who first, in 1882, described 3 cases, considering their origin from epithelial remains of branchial clefts, therefore named these carcinomas branchiogenic or branchial.

As a proof of the correctness of this observation the following two points may be produced, first, the topography of the tumor; second, the fact that the development of carcinomas from the epithelium of the cysts of branchial clefts has several times been proved.

As a rule, the tumor is situated in the upper triangle of the neck, and occupies the place between the hyoid bone and the sternomastoid, whence the tumor develops posteriorly and lies beneath the deep fascia of the neck, forming adhesions with the great vessels, the vagus, and sympatheticus. The location of the tumor with its accepted origin corresponds to the second branchial cleft, the cervical sinus, and the relation which it bears to the bloodvessels is clearly demonstrated by the upward course along the carotids of a branchial fistula.

In isolated cases the tumor appeared in the middle and lower part of the anterior region of the neck, a fact, considered from the developmental history, and from their relationship to bloodvessels, is not clear.

The carcinomatous degeneration of the branchial cysts has been observed in the following cases :

CASE 1.—Bruns reports a case of a 57 year old man who, since 6 months, had noticed a swelling in the upper neck triangle, which on operation was found to be a cyst with hard proliferating walls, situated between the hyoid bone and the large vessels. Microscopic examination showed a pavement epithelial carcinoma, etc.

CASE 2.—Also observed and treated by Bruns. A cystic tumor of 5 months' existence situated at the division of the carotids, which on puncture gave vent to a considerable quantity of yellowish-dark fluid containing epithelial cells. Incision showed the internal surface of a papillary construction; microscopic examination showed pavement epithelial carcinoma with proliferation into the external wall, composed of connective tissue.

CASE 3.—Bruns-Richard. A congenital branchial cyst suddenly suppurated; a fistula with induration remained after incision which after a year's time enlarged and became hard. Microscopically it proved to be an epithelioma.

CASE 4.—Quarry-Silcock incised a tumor of 5 months' growth on the right side of the neck of a man 56 years of age, which proved to be a cyst lined with papillary tissue: microscope showed it to be an epithelioma.

CASE 5.—Observation by von Quarry-Silcock: in the lower third of the sternomastoid of a man 32 years old was located a cyst whose inner layer presented carcinomatous degeneration.

Branchiogenic carcinomas are rare; beside the 8 cases already mentioned are also Gussenbauer's 8 cases; von Reynault's 1 case; Mayor's 1 case; von Eigenbrodt's 1 case; also, possibly, 2 cases reported by von Langenbeck who described them during his time as vessel-sheath tumors; as, also, 1 case published by von Regnault (Czerny) of pavement epithelial carcinoma situated at the place of division of the carotids.

In 1898 I observed 1 case in the left upper neck triangle of an old man which had all of the characteristics of a branchial carcinoma. The extirpation with a resection of the internal jugular and the external carotid was successfully accomplished. Microscope

showed pavement-epithelial carcinoma. The patient succumbed two months after the operation from recurrence in the neck, also gangrene of the leg from thrombosis necessitated an amputation, the autopsy proving the diagnosis of a primary branchial carcinoma.

Symptomatology: So far all of the cases observed have occurred in males and generally in those of advanced years, between 40 and 65. The tumor was oftener located in the right side of the neck. A swelling appears in the typical location which, in the beginning, without causing any pain, slowly enlarges, but in a very few months commences to grow much faster, producing neuralgic pains, radiating particularly into the occipital and ear regions and may be so intense as to rob the patient of sleep. The patient's attention is often directed by the pain to the yet deeply located and slightly prominent tumor.

After a longer progress of the case we may find a neoplasm covered with normal skin, irregular and very hard, situated between the sternomastoid, to which it is firmly adherent, and also fixed to the underlying tissues. On the lower and upper poles may, at times, be felt the pulsation of the carotids.

The regional glands are indurated and the tumor gradually spreads over the entire half of the neck; the skin adheres to the tumor and breaks through the surface, suppurates and produces hemorrhages; internally it ruptures into the great bloodvessels, particularly into the internal jugular, thus leading to metastasis into internal organs. Through the latter, or as a result of local complications, exitus letalis follows.

The course of the disease is rapid, extending from one-half, or at the farthest, to one and one-half years. Diagnosis is very difficult and can only be positively made from the outcome of the case after extirpation, i. e., a cure or an autopsy.

The probable clinical diagnosis is founded upon the discovery of a tumor in the indicated location, sub-fascially situated, whose construction closely resembles a carcinoma, and whose secondary development can be excluded. It is to be remembered that there are hidden carcinomas, for example, in the nose, larynx, esophagus, etc., which it may be impossible to find, while the secondary gland tumor becomes prominent.

The following observation, which I had a chance to make in August, 1898, in this respect, is instructive :

In a man of 63, two hard tumors of about the size of an apple were situated in the right half of the neck, the one of which lay in the upper triangle, and was firmly adherent to the sternomastoid, while the other one appeared some time after the existence of the first and occupied the supraclavicular region.

Because the histologic construction coincided with carcinoma, and, after the most painstaking examination of the cavity of the mouth, of the larynx, and of the esophagus, no primary carcinoma could be discovered, I decided that we had a branchiogenic tumor to deal with, with gland metastasis in the lower triangle of the neck. The extirpation could only be accomplished with the resection of the common, the external and internal carotids, the internal jugular, the vagus, and of the sympathetic. In the jugular a tumor thrombus was found. Death from pneumonia on the fourth day. Autopsy revealed a small carcinoma in the lower third of the esophagus developed in a longitudinal direction and occupying only a small part of the circumference, not at all producing a stenosis of the esophagus, and only infiltrating its walls to a small extent. Above the cardia a cherry-stone-sized carcinomatous gland existed.

The secondary gland carcinomas may frequently be distinguished in the beginning from branchiogenic carcinoma by remaining painless longer, circumscribed,

and movable, while the branchial carcinomas from the beginning are attached to the large bloodvessels, to the nerves, and to the sternomastoid, and early produce pain.

The histologic structure being the same the origin can be shown only when gland tissue is found in the carcinoma. In a case of neck tumor larger than an apple situated in the typical location, which was referred to our clinic with the diagnosis of branchial carcinoma, which, however, seemed doubtful because an examination of the larynx was difficult on account of edematous swelling, a microscopic examination of the extirpated tumor showed pavement epithelial carcinoma with typical lymph follicles in the stroma. It was decided that we had a metastasis of carcinoma in the glands, and later successful laryngoscopic examination demonstrated the existence of carcinoma of the larynx.

The secondary gland carcinomas are to be differentiated from the very rare carcinomas originating from separated lateral offshoots from the thyroid gland whose topography and clinical appearance may very closely correspond with branchiogenic carcinomas. The differentiation of this form of tumors, of which Berger described a typical example, is only histologically possible. Of noncarcinomatous tumors, lymph sarcomas, tuberculous glands, and actinomycosis may, under certain circumstances, be mistaken for branchial carcinomas. The sarcomas are generally of a softer consistency; tubercular glands may be very hard in consequence of fibrous periadenitis, and, since in advanced age they often appear isolated, they might awaken suspicion of malignancy and exploratory incision may have to be resorted to. The combination of hard infiltrations and softened places is characteristic of actinomycosis. The skin becomes involved in the early stages of the disease. The neuralgic pains are not so pronounced in the above-mentioned diseases as in carcinoma. The prognosis is very grave. It appears that extirpation has been followed by only one cure (case of Eigenbrodt).

From the uselessness of other therapeutic measures operative removal should be attempted as early as possible. The operation is difficult as well in the early period of the disease on account of the intimate relation of the tumor with the vessels and nerves. The results of the operation depend upon laying the field widely open; it really means an anatomic preparation, and therefore the utilization of flaps or cross-cuts of Bruns and Gussenbauer recommend themselves. The first cut runs parallel with the anterior border of the sternomastoid; the second runs from the middle of the chin obliquely, or in the shape of a bow, to the middle of the sternomastoid, and eventually to the acromion process of the scapula. The sternomastoid is divided and the four flaps are reflected in the various directions. Should the muscle be involved it must be removed or resected, if free it is tied with catgut. The incision given by de Guervain is to be recommended. It runs along the anterior border of the sternomastoid down to the sternum, thence at an acute angle outward along the clavicle with severing of the sternomastoid about $1\frac{1}{2}$ cm. above its insertion, and with the reflection of the platysma, because it enables one immediately to encircle the large bloodvessels at the lower angle of the wound with silk loops. Owing to close adhesions the internal jugular must always be resected and the carotids many times; one is at times forced to remove the

vagus and sympathetic nerves, which is not serious because of the change in these structures due to the long compression. Considering the difficulties of the procedure and the patients' advanced age, the mortality of the operation is not great. Out of the 8 operated upon by Gussenbauer, only 1 died post-operation from the effects of the ligation of the carotid. The chances of a lasting result are bad.

The only one who remained free from recurrence was the patient of von Eigenbrodt, whom he exhibited at the Twenty-third Surgical Congress. Of the cases of Gussenbauer, 2 died from 5 to 8 weeks after discharge, from recurrence; about the others no report has been made.

Radical operations being impossible in many cases, we are then limited to palliation and symptomatic treatment, curetment, chlorid of zinc, and cauterization.

In the *Surgical Review* (Paris), according to the *Journal of the American Medical Association*, is an article on "Branchial Epithelioma of the Neck," by V. Veau. The following is an abstract:

Six personal observations, added to the 48 on record, show that "malignant branchioma" is not so rare as generally assumed. The treatment should be preventive in case of branchial fistulae, cysts and mixed tumors, by removal before malignant transformation. If ablation of the branchioma is possible it should be extensive. The veins will have to be ligated, but this is free from danger. The artery should be respected, its ablation may entail cerebral accidents, and ligating it to prevent or arrest hemorrhage caused the death of one of Veau's patients. The vagus may have to be resected: this is less dangerous than ligating the primary carotids. It is best not to attempt autoplastics. The branchioma may develop from various elements of the branchial arches and may be located in the parotid and submaxillary glands, or in the thyroid gland, possibly, also, in the mediastinum, but it is most frequent and most typical in the neck.

THE RESOURCES OF MODERN MINOR GYNECOLOGY.*

By AUGUSTIN H. GOELET, M.D.,

of New York.

Professor of Gynecology in the New York School of Clinical Medicine, etc.

THIS paper has been suggested by the growing tendency to lose sight of the capabilities of minor gynecology as shown by the assertion of some men that they find little use for it, but after examining their patients, they are sent to the hospital.

Is gynecology becoming a surgical specialty? If so, I desire to enter an earnest protest. There is much we can accomplish by minor gynecology. There are many gynecological disorders that are curable by office treatment.

But the man who limits his resources to glycerin tampons and iodine applications, is truly in a sad plight and there are few cases that he can cure without resort to surgery. It must be admitted that not all gynecological disorders are amenable to nonsurgical treatment, and I would not be understood as being opposed to surgical gynecology. I am heartily in favor of any method of treatment that gives the best results for the patient. But the growing indifference to nonsurgical treatment or minor gynecology seems to me an error. The multiplicity of our modern gynecological resources shows that we are better equipped than we were 15 or 20 years ago. Yet many of these cases

* Read at the meeting of the New York State Medical Association held at New York, October 15 to 18, 1900.

were cured even then. May we not, by exercising a little more patience and perseverance, avoid much needless surgery? Is it not our duty to conserve, rather than to destroy?

It has occurred to me that it might be profitable to enumerate some of our modern gynecologic resources and consider what they may aid us in accomplishing. Our resources may be divided into diagnostic and therapeutic.

DIAGNOSTIC RESOURCES.

Microscope.—Foremost among diagnostic resources is the microscope. It occupies the position of a preventive resource, since by the early detection of infection through its aid, many of the more serious gynecological disorders may be averted. I believe I am not demanding too much when I say no man should practise gynecology, or even examine gynecologic cases, unless he possesses this means of investigating the character of vaginal discharges, and the knowledge to employ it intelligently. This applies to the general practitioner as well as to the specialist. It is unnecessary to remind you that many lives have been wrecked and many lost, by neglect of proper investigation of vaginal discharges, both in women and children. This is a diagnostic resource that none of us can afford to neglect, or be without, and is one very important advantage we have over our predecessors of a quarter of a century ago.

Uterine Endoscope.—This is comparatively a new diagnostic instrument, and the one I show you, which illuminates the field by means of a small electric light carried down to nearly the end of the tube, is one which I presented in connection with my paper on the "Treatment of Endometritis by Drainage and Irrigation" last year at the Columbus meeting of the American Medical Association. The advantages of this instrument as an aid to diagnosis in conditions involving the interior of the uterus, cannot be appreciated until it has been used. One of its chief advantages is in showing when curettage is necessary and when it is not necessary, and also showing when the work has been done thoroughly.

Cystoscope.—It is not necessary to enter into the details of the uses of this instrument. Its utility is now very generally recognized and no well-equipped specialist in this line is without one. It is positively indispensable for diagnosis of diseases involving the interior of the bladder.

Steel Dilators.—After the sponge-tent was abandoned, because of its liability to cause sepsis, the steel dilator came more generally into use, and there are a dozen or more varieties on the market. The advantage of this instrument, as a means of diagnosis, by affording facility for exploration of the interior of the uterus, is too well recognized to require more than passing mention. The usefulness of the two-branch dilator is, however, limited, since with it only a comparatively small degree of dilation can be accomplished. When the cervix is rigid, sufficient dilation to permit the introduction of the finger for exploration cannot be accomplished with this instrument. The four-branch dilator has been made to extend the degree of dilation of the cervix, and answers the purpose better than any of its kind that I have used. It is, however, a powerful and dangerous instrument in careless hands and should be used with extreme caution.

We have never had anything that produced such

thorough and satisfactory dilation of the cervix, as the sponge or laminaria-tent, and I am sure that I am not alone in feeling deep regret in being obliged to abandon them. Very frequently cases are encountered in which exploration of the cavity with the finger is desirable, yet the cervix is too rigid to be dilated safely with the steel dilator.

Recognizing this, I was induced to devise a plan of employing them in a manner that would be perfectly aseptic. The outcome is this rubber tent-cover that is made for me by the Miller Rubber Company. To fully appreciate its advantage, we must consider why a sponge or laminaria-tent could never effect aseptic dilation of the cervix when used bare. It is certainly possible to render the tent aseptic, but its expansion depends upon absorption of the secretion from the surface with which it is in contact. Hence the secretion from the cervical glands, which so frequently harbors bacteria, is taken up by the tent and conveyed to the cavity above, where the bacteria find a fertile field for development.

By using the tent-cover, this is avoided, because the tent expands within it. A strip of gauze is carried up along the side of the tent and over the end, one end of the gauze being left long. This is wet and the cover is slipped on over it and it is then introduced into the cervix. One end of the gauze is left hanging from the mouth of the cover in the vagina. The vagina is now filled loosely with gauze and this is made thoroughly wet. The capillary action of the gauze carries the moisture from that in the vagina to the tent and causes it to expand within the cover. Therefore, even if the vagina is not sterile, there is no risk of infecting the endometrium from that source.

Anesthesia.—Anesthesia, whereby unconsciousness of pain and relaxation may be acquired to facilitate examination by palpation in doubtful cases, where the patient is too sensitive to permit a satisfactory examination, is of inestimable value, as a means of diagnosis. This advantage is only too self-evident. Increased dexterity in bimanual palpation acquired by practice, and the positions of the patient which have been found to facilitate these examinations, make examination under anesthesia less frequently necessary than formerly, but this can only be attained by a few who have unusual facilities and know how to utilize them to the best advantage.

Greater familiarity with the pelvic organs and abnormal growths in the pelvis, afforded by abdominal section, is one of the many advantages we, of the present day, possess, and which was denied us before these operations became so frequent. The immense aid this is to one's diagnostic ability cannot be appreciated until one has had this experience.

Exploratory Abdominal Section.—Finally may be mentioned exploratory abdominal and vaginal section. This is a diagnostic resource of great value, since it is now a recognized procedure in doubtful conditions within the pelvis or abdomen, where it has been impossible otherwise to reach a conclusion.

THERAPEUTIC RESOURCES.

It is a mistake to think that our therapeutic resources are few. I find them more numerous and more efficient than when I began this line of work 16 years ago. I regret that I have only time to give a brief review of those that seem to me the most important.

The Vaginal Tampon and Local Applications of Iodin.

—The vaginal tampon and local application of iodine are given first place, not because they are the most invaluable or the most indispensable of our therapeutic resources, but rather because they have held first rank to long. It cannot be denied that they still serve a very useful purpose in the treatment of gynecologic disorders, especially those of a chronic inflammatory character, and I do not wish it to be inferred that I discredit their usefulness, but I think too much is attributed to them and they are often misapplied.

The application of iodine to the vaginal vault is certainly beneficial in certain chronic inflammatory conditions about the uterus and bladder. It relieves pain and soreness, stimulates absorption of inflammatory exudates, and is the most reliable local antiseptic that can be employed. Therefore, it is particularly useful in counteracting infection about the cervix and even within the uterus when it is properly applied. It should not be applied to the interior of the uterus, however, in full strength, nor upon a cotton-wrapped applicator, but should be diluted with water and applied through a double-current irrigator, when the canal of the cervix is sufficiently patulous to permit free drainage afterwards.

Tampons soaked with glycerin are useful for effecting depletion of the pelvic structures, but they cause discomfort and do harm if not properly used or if they are retained too long, by exerting pressure upon sensitive structures. There are some improvements in the method of using this agent that have been suggested by personal experience. For instance, if the glycerin is applied on a strip of absorbent gauze that is distributed loosely and evenly against the vaginal vault around the cervix, there is less discomfort than from the application of tampons soaked in glycerin. The patient should be placed either in the Sims' or knee-chest position for its insertion. In some instances, when even less pressure than this latter exerts can be endured, I have employed glycerin by placing the patient in the knee-chest position, inserting a perineal retractor and pouring about half an ounce of glycerin into the vagina from a small test-tube. Then a flattened tampon of nonabsorbent cotton is placed just within the vulvar orifice to retain it in the vagina. The patient, when possible, should retain the recumbent position for an hour or two afterwards.

I have found glycerin and iodine combined, in the proportion of 1 part to 32, more satisfactory than boroglycerid, or ichthyol and glycerin. It is an excellent astringent and possesses all the advantages of the other two remedies mentioned, with none of their disadvantages.

The dry-wool tampon is a very useful elastic support for the uterus, when the pelvic structures are too sensitive for the unyielding pressure of a pessary, and by applying it at first, the parts are prepared for a more permanent and reliable support. Thus the sensitive structures are gradually made accustomed to pressure and the uterus is lifted in the pelvis, thereby relieving the obstruction to the return circulation and reducing the weight of the organ. When used for this purpose, the surface of the vagina and tampon should be coated with some bland, nonirritating antiseptic powder, to keep the tampon from becoming foul and prevent irritation of the vaginal surface.

These tampons are best introduced with the patient in the knee-chest position, and care must be taken to adjust them so they will support the uterus in the de-

sired position, without exerting unequal pressure at different points.

Pessaries.—The pessary is certainly a very useful artificial support for the uterus, but it should be regarded only as an auxiliary to other measures in effecting a cure. Unaided, it can accomplish little. Unfortunately, past teaching has caused too much to be expected of it. An enumeration of its uses and abuses would constitute a chapter in itself and would take up too much space here.

Uterine Irrigation.—I regard uterine irrigation one of the most important additions to our gynecologic resources, because it is the only reliable method of cleansing the uterine cavity and it affords the most effective method of application to the surface of the endometrium. If it has not already done so, it should supersede all other methods of application to the interior of the uterus. The clinical irrigator which I show you makes it possible to employ this method without previous dilation of the canal of the cervix and without an anesthetic. Therefore it may be used in office or clinical work, without discomfort to the patient and without risk if asepsis is observed. It is small enough to be introduced, in most cases, with ease, and when it does not pass the internal os readily, it is converted temporarily into an electrode, by slipping a piece of rubber tubing over it for insulation and connecting it with the negative pole of the battery (galvanic). By using 10 M. for half a minute or a minute, the obstruction is overcome. If the current is continued while the irrigation is going on, thorough relaxation of the canal is produced for subsequent drainage. The outer tube of this instrument is made long, that the outflow may escape outside the vulvar orifice. It can be employed in the dorsal or lateral position.

It would consume more time than I am allowed to enumerate the advantages of uterine irrigation. They should be sufficiently self-evident to make it unnecessary.

Electricity.—Despite the fact that the purely surgical gynecologists have tried to kill it, that they have repeatedly declared it dead, that the enthusiasts have mortally wounded it by their exaggerated claims, and that it has failed or done harm when employed indiscriminately and incompetently, it is still very much alive and is doing much good. The gynecologist who does not employ electricity, neglects one of the most valuable gynecologic resources. It will not be possible here to give you more than a mere suggestion of its capabilities in gynecologic disorders.

Galvanism.—Galvanism, or the direct current, will relax the cervical canal and promote drainage of the cavity above and of the submucous glands of the cervix as well, establishing thereby a condition essential for the cure of endometritis, which cannot otherwise be done except by surgical intervention. It will dispel pelvic congestion, relieve pain depending thereon and promote absorption of exudates and effusions more satisfactorily than any other agent, except faradization. It will relieve the symptoms and reduce the size of certain varieties of fibroid growths in the uterine wall and when they have not attained too great a size, or have not acquired extraneous nutrition through organized adhesions with adjacent structures, they sometimes disappear under its use.

Faradization.—In faradization we have a most effective remedy for the relief of pelvic pain and congestion; for promoting rapid absorption of effusions and

exudates, and for the cure of both acute and chronic inflammatory conditions in and about the uterus. As a remedy in the above named conditions, it is without an equal. I cannot consume the time here to explain how it produces these results. A correct appreciation of its physiologic action will render such explanation unnecessary.

Internal Medication.—The administration of remedies that act through the general circulation and exert some special action upon the generative apparatus, is very generally understood. It is only necessary to warn against expecting too much of them to the exclusion of local measures, as the busy practitioner is inclined to do. There are a few internal remedies which, from personal observation, I have found particularly valuable as auxiliaries that deserve special mention here.

A combination of bromid and potassium iodid (10 grains of the former and 5 of the latter), given in water 3 times a day, is particularly beneficial as a sedative for painful conditions in the pelvis and for promoting absorption of inflammatory exudates.

The ordinary compound cathartic pills, given one every second or third night, is one of the most satisfactory remedies for chronic constipation so common in this class of cases. Unlike other cathartics, the dose does not have to be increased, but owing to their stimulating action on the liver, it is kept active and they can soon be dispensed with. I have never observed any undesirable action from the calomel they contain.

The bromid of gold and arsenic I have found very serviceable as a sedative to the pelvic circulation and to the generative apparatus in general; particularly when there is ovarian irritation, and in anemic conditions. It produces marked diminution in the menstrual flow, even where the endometrium is in a condition to demand curettage. For this reason it is effective in menorrhagia and metrorrhagia, but it would not be appropriate where menstruation is deficient except when due to anemia.

I fully realize that I have not done my subject justice and I have omitted much that is important. My excuse is the limited time at my disposal here. But if what I have said proves an incentive to renewed efforts in the line of minor gynecology, which I feel has been much neglected of late, I shall be repaid for the effort I have made in this direction.

THE HOME MODIFICATION OF MILK FOR INFANT FEEDING.

By L. EMMETT HOLT, M.D.,
of New York.

EVERY physician who engages in infant feeding must know something of milk modification. The milk laboratories have taught us the great advantage of accuracy and definiteness, and the percentage method has been of very great assistance in the modification of milk at home. While it may be said that accuracy carried to small fractions of a percent is not absolutely necessary for practical results, it is a matter of the greatest importance that the physician know very approximately what he is feeding. There is great need of a simple method of calculating readily the proportions of fat, sugar and proteids, in formulas to be made up at home. It must be easy also to vary the proportion of these different ingredients separately. A method to be really useful at the bedside must be one requiring the minimum

amount of arithmetical calculation, and so simple as to be grasped by the average nurse or mother who is to prepare the food. While all of the 3 or 4 different methods proposed secure, I have no doubt, equal accuracy with the one here given, most physicians have found them too complex for use. It is greater simplicity which is aimed at in this paper.

No method of home modification secures more than approximate accuracy; since the exact composition of the elements—milk and cream—which are used, it is not ordinarily possible to know. There are, however, some general facts, which may prove of great assistance to the physician in making his calculations. The composition of herd milk, or mixed milk of a number of cows, is practically constant except in the proportion of fat, this varying from 3.50% to 5.50%; in the ordinary samples used 4% perhaps may be taken as the average, except that from Jersey herds. As regards the proteids, it seems certain from recent analysis, that in assuming 4% as the average we have made a mistake, and that 3.50% is much nearer the truth. Some of the foreign authorities place it as low as 3.40%, others at 3.60%, but very few as high as 4%. The sugar is not far from 4.30% to 4.50%. We shall therefore assume in our discussion the composition of average herd-milk to be: fat 4%, sugar 4.50%, proteids 3.50%.

It is necessary to know also the percentages of sugar and proteids which are present in cream containing different amounts of fat. The following table, taken chiefly from the analyses made by Adriance, and confirmed by other observations, may, I think, be taken to represent pretty nearly the composition of creams of different density:

	I.	II.	III.	IV.	V.
Fat	4.	8.	12.	16.	20.
Sugar	4.50	4.35	4.21	4.05	3.90
Proteids	3.50	3.40	3.30	3.10	3.05
Salts75	.70	.65	.60	.55

In most of the modifications of milk for young infants it is required that the fat be considerably higher than the proteids. A simple plan would seem to be first to raise the percentage of fat to such a point, that, when the milk is diluted to reduce the proteids to the required figure, the fat shall also be reduced to the percentage which we wish to use. Really the important part of the modification consists in finding the best way of introducing the extra fat desired. It may be done by the addition of cream, or by using the upper milk after it has been standing for a given length of time.

If cow's milk from a mixed herd is put into bottles soon after it is drawn and rapidly cooled, it will be found that after 4 hours the upper fourth will contain nearly all the fat that will rise as cream; and that the upper layers will have nearly the same percentage of fat, whether the milk has stood for 4 hours, for 8 hours, or over night (16 hours). This has been demonstrated in a series of experiments made for me by Messrs. Upton and Jeffers at the Walker-Gordon Farm at Plainsboro. After standing under the conditions mentioned, fat tests were made with the Babcock apparatus of the different four-ounce layers of bottled milk which were carefully removed with a siphon, with the following results:

	After 4 hours.	After 8 hours.	Over night.
Upper 4 ounce.	20.50% fat.	21.28% fat.	22.00% fat.
Second "	6.00 "	6.50 "	6.50 "
Third "	1.50 "	1.40 "	1.00 "
Fourth "	1.20 "	1.00 "	.30 "
Fifth "	1.10 "	1.00 "	.05 "

Each of the above percentages represents the averages, each test having been repeated many times, 110 different

varies between 4.05% and 4.50%. A mixture which contains $\frac{4}{20}$ milk will have, before any sugar has been added, 80% or 90% sugar. If one ounce of sugar is added to each 20 ounces of the mixture, which alone would make the sugar 5%, it will now be raised to 5.80% or 5.90%, according as we use the primary formula of series A or E. In practice this may be considered as a 6% sugar.

If we take a formula containing $\frac{9}{20}$ milk, the milk mixture will give 1.85 or 1.95 sugar, according to which primary formula we are using. The addition to this of one ounce of sugar to each 20 ounces of the mixture will raise the total to 6.85% or 6.95%, practically the 7% sugar.

Lower percentages of sugar, when desired, are readily secured by making the quantity added less than 1 ounce to each 20 ounces of food.

In measuring the milk-sugar it is to be remembered that 1 ounce by volume is very nearly 1 ounce by weight. If the measuring is done with the tablespoon, one even tablespoon may be calculated as 3 drams, or $2\frac{1}{2}$ even tablespoonfuls as 1 ounce. If cane-sugar is used, the proportions should be about one-half that which has been mentioned, *i. e.*, one-half ounce to each 20-ounce mixture; as there are few infants who will bear cane-sugar in the proportion of 5% to 7% in their food.

Lime Water.—It is generally agreed that 5% lime water has the average alkalinity which is required. This is easily secured by adding 1 ounce of lime water to each 20-ounce mixture. More than this may be used without disturbing the calculation.

Diluent.—For my own part I prefer boiled water as a diluent for the first months of life. However, the method of modification is not affected if anything else is used. One may, if he prefers, use one-half or one-quarter of barley water, or the dilution may be entirely with this. The milk sugar is, of course, to be dissolved in the diluent whatever it may be.

In all the formulas given the amount of water or of the diluent is to be added in a sufficient quantity to make up 20 ounces, this unit being the most convenient one for calculation. The quantity of the mixture may be increased to 25, 30, 35 or 40 ounces by simply using of each ingredient, $\frac{1}{4}$ more, $\frac{1}{2}$ more, $\frac{3}{4}$ more, or twice the amount.

The foregoing detailed description of the different steps in the process of modification may, perhaps, make this method seem very complex. However, the practicable application of the results is very simple. Below are given the various proportions derived from the different primary formulas, carrying out the principles thus described. I have written out those which contain the fat from about 0.5% to 4.0% with the combinations in the proteids with which they are likely to be used. Of course, the number of these derived might be indefinitely increased.

SERIES A.—Ratio of fat to proteids 5:1.

Primary Formula.—16% milk (or cream) containing fat=16, sugar 4.05, proteids 3.20%. This being the upper 6 oz. of 1 quart of bottled milk, as above described, or the ordinary gravity cream.

Derived Formulas Giving Quantities for a 20 oz. Mixture.

I.	{ Sugar 1 oz. Lime water 1 oz. Water q. s. 20 oz. }	with 1 oz. 16% milk	fat .80, sugar 5.20, proteids .16%
II.	" " " " 2 oz. " " "	" 1.60, " 5.40, "	.33%
III.	" " " " 3 oz. " " "	" 2.40, " 5.60, "	.48%
IV.	" " " " 4 oz. " " "	" 3.20, " 5.80, "	.64%
V.	" " " " 5 oz. " " "	" 4.00, " 6.00, "	.80%

If more than the 20 oz. mixture is needed, it is convenient to calculate the amount as 25, 30, 35, 40 oz., etc., thus using

16% milk	2 oz.	To make	Milk	24 oz.	To make	Milk	8 oz.
Milk sugar	1 oz.	25 oz.	Sugar	1 1/4 oz.	30 oz.	Sugar	1 1/2 oz.
Lime water	1 oz.	add	Lime water	1 1/4 oz.	add	Lime water	1 1/2 oz.
Water q. s. 20 oz.	1/4 more.	Water q. s. 25 oz.	1/2 more.	Water q. s. 30 oz.			

If the formulas intermediate between these are needed, the increase in the 16% milk may be made by $\frac{1}{2}$ ounce instead of 1 ounce; *e. g.*, a formula between II and III may be obtained by using $2\frac{1}{2}$ ounces, which will give fat 2%, proteids .40%.

SERIES B.—Ratio of fat to proteids 4:1.

Primary Formula.—13% milk = fat 13.0; sugar 4.15; proteids 3.25% obtained (1) as upper fourth of bottled milk; or (2) by mixing 1 part milk (4%) and 3 parts cream (16%).

Derived Formulas Giving Quantities for 20 oz. Mixture.

I.	{ Milk sugar 1 oz. Lime water 1 oz. Water, q. s. 20 oz. }	with 1 oz. 13% milk=fat 0.65, sugar 5.20, proteids .16%									
II.	" " " "	"	2 oz.	"	"	"	1.30,	"	5.40,	"	.33%
III.	" " " "	"	3 oz.	"	"	"	2.00,	"	5.60,	"	.50%
IV.	" " " "	"	4 oz.	"	"	"	2.65,	"	5.85,	"	.65%
V.	" " " "	"	5 oz.	"	"	"	3.30,	"	6.00,	"	.82%
VI.	" " " "	"	6 oz.	"	"	"	4.00,	"	6.25,	"	1.00%

In this series as in the preceding one, formulas intermediate between those given can be readily made; the directions for making mixtures of 25 ounces, 30 ounces, etc., are also the same, *viz.*, by taking one-fourth more, or one-half more of each of the ingredients.

SERIES C.—Ratio of fat to proteids 3:1.

Primary Formula.—10.0 milk = fat 10%, sugar 4.30, proteids 3.30% obtained (1) as upper one-third of bottled milk; or (2) equal parts of milk (4%), and cream (16%).

Derived Formula Giving Quantities for 20 oz. Mixture.

I.	{ Milk sugar 1 oz. Lime water 1 oz. Water q. s. 20 oz. }	with 1 oz. 10% milk	= fat .50, sugar 5.20, proteids .17%
II.	" " " " 2 oz. " " "	" 1.00, " 5.40, " .33%	
III.	" " " " 3 oz. " " "	" 1.50, " 5.60, " .50%	
IV.	" " " " 4 oz. " " "	" 2.00, " 5.85, " .66%	
V.	" " " " 5 oz. " " "	" 2.50, " 6.05, " .83%	
VI.	" " " " 6 oz. " " "	" 3.00, " 6.25, " 1.00%	
VII.	" " " " 7 oz. " " "	" 3.50, " 6.50, " 1.17%	
VIII.	" " " " 8 oz. " " "	" 4.00, " 6.70, " 1.35%	

SERIES D.—Ratio of fat to proteids 2:1.

Primary Formula.—7% milk = fat 7.00, sugar 4.40, proteids 3.40% obtained (1) by using the upper one-half of bottled milk, or (2) by using 3 parts of milk (4%) and one part cream (16%).

Derived Formulas Giving Quantities for 20 oz. Mixture.

I.	{ Milk sugar 1 oz. Lime water 1 oz. Water q. s. 20 oz. }	with 1 oz. 7% milk	= fat .35, sugar 5.20, proteids .17%
II.	" " " " 2 oz. " " "	" .70, " 5.40, " .35%	
III.	" " " " 3 oz. " " "	" 1.05, " 5.60, " .52%	
IV.	" " " " 4 oz. " " "	" 1.40, " 5.80, " .70%	
V.	" " " " 5 oz. " " "	" 1.75, " 6.00, " .87%	
VI.	" " " " 6 oz. " " "	" 2.10, " 6.20, " 1.05%	
VII.	" " " " 7 oz. " " "	" 2.45, " 6.45, " 1.22%	
VIII.	" " " " 8 oz. " " "	" 2.80, " 6.70, " 1.40%	
IX.	" " " " 9 oz. " " "	" 3.15, " 6.90, " 1.55%	
X.	" " " " 10 oz. " " "	" 3.50, " 7.10, " 1.73%

Formulas marked with the asterisk in the last two series are the only ones in which a special calculation of the sugar needs to be made; the usual amount of sugar, 1 ounce to a 20-ounce mixture, gives, as is seen, too high a percentage. It is seldom that infants taking the high percentages of fat and proteids of these formulas require the sugar to be even as high as 7%. A good working rule for the average case is to add only $\frac{3}{4}$ ounce to each 20 ounces for a formula containing $\frac{1}{20}$ or $\frac{1}{20}$ milk; and above that not more than $\frac{1}{2}$ ounce.

Application of these Formulas in Infant Feeding.—This is by no means so simple as their calculation. I seldom use series A and B with healthy children of average digestion. They are inserted here because they are occasionally advantageous; but for the vast majority of

healthy infants it is rarely necessary to have the fat more than three times the proteids.

For healthy infants, the first 15 months may be considered as made up of three feeding-periods. For the first one, extending from birth to the end of the third or fourth month, the best results are obtained in my experience when the fat is three times the proteids, or the ratio existing in good breast milk.

The second period extends from the end of third or fourth month to about the end of the tenth month. During this time the increase in the strength of the food should be made chiefly of the proteids. With most children the best results are obtained in this period when the fat is twice the proteids.

The third period extends from the end of the tenth month to the beginning of the fifteenth. During this the proteids are gradually increased until they are nearly equal to the fat, or, in other words, until the child is taking whole milk.

For the first period the formulas of series C are to be advised. No other primary formula than the 10% milk need be considered until the infant is three or four months old. The newly-born child can usually begin with No. II of this series—fat 1.00, sugar 5.40, proteids .33%—but seldom, I think, with a higher formula. The percentages are gradually raised as the child becomes accustomed to taking cow's milk, until No. VI or No. VII, 3.5—6.5—1.17, is reached. From this point a healthy infant would probably pass to No. VII of the series D, and the proteids would be rather rapidly raised until No. IX is reached. This with Nos. X and XI will carry a healthy infant until the end of the tenth month. From this time until the child is able to take whole milk such formulas as Nos. VII and VIII of series D may be used.

The low percentages of fat and proteids given in the first three or four formulas of the last two series are applicable for those infants who in the early months have special trouble with the fat, and, at a later period, for many who suffered from fat-indigestion. For many of these abnormal cases, the fat must often be made, at least for the time being, nearly or quite as low as the proteids.

The formulas of Series A and B, where the fats are very much higher than the proteids, are useful in a few infants during the early months who have special difficulty in digesting the proteids, but who are able at the same time to take without difficulty relatively high fat. Both these series of formulas I find occasionally of service for short periods, but I do not think they are so generally useful in the early months as the slightly lower fats of series C.

Conclusions.—In the foregoing discussion we have considered only the modification of the milk elements. All other discussion of infant-feeding is foreign to our purpose.

Three primary formulas can be made to do duty for the entire year for the vast majority of healthy infants.

By the method of calculation here given on the basis of $\frac{1}{20}$ it seems to be much easier to pass from one formula to another of the same series than by other methods. Since the additions of sugar and lime water are constant, it is necessary only to calculate the percentage milk is increased by an ounce in each 20-ounce mixture. The diluent water is in all cases added in sufficient quantity to make the total.

Larger quantities than 20 ounces can easily be calculated if our increase is made by 5; e. g., for 25 ounces

$\frac{1}{2}$ more of the milk, the sugar and the lime water; for 30 ounces $\frac{1}{2}$ more, etc.

In securing the primary formula my preference is either for milk fresh from the cow, or the bottled milk, rather than for the mixtures of milk and cream, mainly for the purpose of securing greater freshness. Where milk is obtained fresh from the cow, if it is placed in a bottle and rapidly cooled in the manner indicated, not only will the cream rise quickly so that the food may be made up when the milk is only 4 hours old, but at the same time this rapid cooling is of the utmost advantage in checking the early fermentative changes in milk.

In taking the milk from the top of the bottle it is to be remembered that the entire number of ounces specified for the primary formula should be taken, although it may not all be needed to make up the milk for weaker formulas.

A CRITICISM OF THE DIAGNOSIS "COMPOSITE TERATOMA OF THE OVARY" MADE IN THE "PATHOLOGICAL REPORT" OF DR. E. A. JONES.

By S. W. BAUDLER, M.D.,

of New York City.

In the PHILADELPHIA MEDICAL JOURNAL of December 22, Dr. Edgar Allen Jones reports, through the courtesy of Dr. W. E. B. Davis, "A Composite Teratoma of the Ovary," accompanied by a pathologic report. This so-called "teratoma" contains more recognizable bones than any other teratoma whose description I have observed. Besides, the cranial bones were recognized and "parts of the lung, liver, the stomach, and about 60 cm. of the intestine" were found. A teratoma is simply a solid dermoid cyst, and it is a question of interest to correctly classify this tumor. We are told that "the tumor filled up the left side of the pelvis and was attached to the uterus by a large pedicle," and that "the fetus has the appearance of having reached the sixth or seventh month of fetal development." We are not told, however, whether the tumor was firmly imbedded, whether adhesions were present, whether it was intraligamentous, etc. As no mention is made of placenta macroscopically, and no mention is made of the examination of the entire specimen for such tissue, we are left in doubt as to this side of the question. Though called "teratoma" of the ovary, the microscopical examination makes no mention of the presence of ovarian tissue in the capsule, but an anatomical diagnosis is made of "composite teratoma, combined with cystic adenoma of the ovary." Although certain portions of the tumor contain skin, no mention is made as to whether the skin covered the fetus or lined the cyst cavity.

The statements, however, concerning the presence of vertebrae, of too well developed scapula and other skeletal bones are so positive that we are supposed to take their presence for granted. Going on this supposition I cannot believe that the case is one of teratoma. With the exception that no mention is made of the presence of placental tissue, I see no reason why the author changes the opinion conveyed in the following statement: "The most interesting feature of this case is the fact that the fetus was so large, and, on casual observation, so well formed, that it could easily be mistaken for ectopic gestation which had ruptured into the

cavity of a preexisting ovarian cystoma. As has been stated above, the diagnosis of ectopic pregnancy had been made from the history of the case." Referring to the history given by the author, it is evident that such a diagnosis was quite naturally made, and I see no reason in any portion of the report for changing this view. Dr. Jones mentions the various theories as to the origin of dermoids and teratomata, and says: "The theory of the development of an ovum without impregnation—parthenogenesis—has some supporters. Cohnheim's theory of embryonal remnants, capable of producing different kinds of growths (dependent upon the type of the cell), is reasonable, but it is strange why so many of these growths occur in the ovary. The theory which has the greatest support by the greatest number of observers is that of fetal inclusion, *i. e.*, the inclusion within the body of a developing fetus, the remains of an imperfectly developed twin. This, too, is subject to the criticism applied to Cohnheim's theory, but it seems more plausible than any of the others. Finally, it must be admitted that the pathogenesis of the teratomata is very obscure."

The inclusion, within the body of a developing fetus, of the remains of an imperfectly developed twin, and especially the development of such an inclusion in the ovary, is a theory which is today no longer earnestly considered. The prevailing idea as to the origin of dermoids and teratomata of the ovary depends on the statements of Wilms and Pfannenstiel that these tumors contain products of all three blastodermic layers, if not macroscopically yet microscopically. This theory rests further on the microscopical investigations of Wilms, who believes that he finds the various structures in an arrangement corresponding to that in the normal fetus, such as scalp, brain, central canal, respiratory tract, etc. This theory is further defended by the descriptions given by various authors of the presence in dermoid cysts of fingers, mammae, eyes, ribs, pelvic bones, trachea, intestinal-like structures, etc.

The statement of the possibility of a parthenogenetic development of an ovum is supported by Wendeler. He considers the further growth of a nonfertilized human ovum to be possible on analogy with the segmentation observed in the nonfertilized ova of the frog, the hen, and the rabbit.

The following may be said against these statements:

1. No dermoids or teratomata of the ovary or ligamentum-latum contain more than the products of ectoderm and mesoderm. Entoderm is never present.

2. The arrangement and order of the above-mentioned microscopical areas is only an accidental grouping and has nothing to do with the formation of a fetus, as may be seen from the drawing No. 130 in Martin's "Diseases of the Ovary," 1899.

3. All the above-mentioned organs and structures have been described because of "a resemblance." Küster found in a dermoid situated between the bladder and the uterus a bone "which without doubt may be called a rib," and a flat bone "which I cannot definitely classify, perhaps a pelvic bone." Baumgarten mentions a formation "which has a slight resemblance to a fetal eye." Concerning other areas he says: "All in all, sections furnished a no slight resemblance to sections through the embryonal stomach and intestine."

In this manner, without any positive proof, the theory of parthenogenesis has been built up. Even though we were to grant the occurrence in ovarian dermoids of various tissues of the head, and other portions of the

body, it would still remain an inexplicable question why these various structures occur singly, and why more complete arrangements are not present. Those areas which resemble the stomach and intestinal glands are nothing but cystadenomatous areas, and are in harmony with the real explanation of the origin of dermoid cysts. They are, like them, due to the development of regressive structures or displaced cells.

4. The authors whom Wendeler quotes and who have observed the segmentation of nonfertilized ova say "that these ova always go to destruction." Hensen, whom he quotes, says that this segmentation has nothing in common with the division of a fertilized ovum, and that a parthenogenesis is not to be thought of. Spee and Nagel say the same. The previously accepted view of a parthenogenetic segmentation of the hen's egg is now proved to be due to a fertilization by dying spermatozoa. Barfurth and Lau have shown that the parthenogenetic development of the bird's egg is only an irregular segmentation. Sobotta asks whether, after all this, we can really sensibly believe in such a process in the ova of mammals.

The most peculiar tissue found in dermoid cysts is represented by teeth, which may be milk or second teeth. Since I absolutely deny the origin of these tumors through parthenogenesis it is necessary to explain the origin of these tumors. These tumors result from displaced ectodermal and mesodermal cells, and wherever ectoderm and mesoderm are present teeth can be formed. They are found in dermoid cysts of the brain, of the eye, of the neck, of the mediastinum, of the abdomen (retroperitoneal), of the ovary, etc., and have as such no specific value. These ectoderm and mesoderm cells are displaced into the ovary by the Wolffian duct and the Wolffian body. It is generally granted that the Wolffian duct originates near the ectoderm, but Spee has shown that it originates from the ectoderm and that the Wolffian body as well as the germinal epithelium of the ovary are of ectodermal origin. In this way the ovary, the tube (duct of Müller) and uterus, *i. e.* the epithelium of the two latter, are of ectodermal origin, and not, as is generally believed, mesodermal. It would indeed be strange if we were to continue in the belief that mesoderm is capable of producing epithelium. The Wolffian duct, and the Wolffian body, which takes an important part in furnishing the ovary with its stroma, may carry then into the ovary ectodermal and mesodermal cells, for they originate from ectoderm and lie in mesoderm. The Wolffian duct and the Wolffian body are situated at the hilus of the ovary as the parovarium and the paro-phoron, and not infrequently their tubules are found to penetrate into the structure of the ovary itself. The development of these tubules alone is the cause of the ovarian cystic tumors, especially the cystadenomata. If ectodermal and mesodermal cells are likewise displaced, we find then a dermoid cyst or a teratoma, very frequently combined with a cystadenoma in the same or other ovary.

As regards the teeth, Olshausen says: "They have, like the teeth of the mouth, a crown sloping toward the median line of the body, so that from the teeth the side from which the cyst was removed may be diagnosed." Holländer called Olshausen's attention to this fact, and every time that the latter put him to the test Holländer diagnosed correctly the side of the cyst. Twelve cysts containing teeth were examined for me and in no case were right and left teeth found in the same cyst. In

all the cases (six) in which the history stated the side from which the cyst was removed, the statement of Waldberg, who examined the teeth, was found to be correct. Since ectoderm, cartilage, and bone are present in practically every dermoid cyst of the ovary, teeth are easily formed, for, as Hertwig says, "the teeth are originally nothing but ossified papillae of the skin and mucous membrane."

The suprarenal bodies lie close to the genital organs in the early embryonal period, and it is said that the sexual band of the Wolffian body is concerned in the formation of the suprarenal body. When we consider that portions of the suprarenal bodies may be found in the ligamentum-latum, it is easy to grant that cells or cell-groups of the ectoderm and mesoderm which are in the closest relation to the Wolffian duct and the Wolffian body may be displaced by them into the hilus ovarii. For that reason, too, a dermoid cyst may be found in the ligamentum-latum without involvement of the ovary.

In the dermoid cysts of the ovary ectoderm products are present as squamous epithelium, sweat glands, sebaceous glands, hair, glia tissue, etc., and as glandular structures lined with squamous epithelium, ciliated epithelium, or cylindrical epithelium. Mesoderm products are present as cartilage, or bone, or teeth (partly ectoderm), connective tissue, muscle (almost never striated muscle), fat tissue, etc. *No organs, as such, are present, and pancreas, liver, and lung have never been described, though Wilms makes indefinite statements concerning the lung.*

The following reasons are therefore to be raised against the theory of parthenogenesis: 1. The dermoid cysts of the ovary contain products of ectoderm and mesoderm only. 2. The development of the various structures without placenta. 3. The continued growth of such a rudiment with the formation of long hair and second teeth. 4. The frequent occurrence of bilateral dermoids. 5. The occurrence of several dermoids in one ovary. 6. The occurrence of dermoids in the ligamentum-latum without involvement of the ovary. 7. The decided growth of these tumors at or after puberty, and their occurrence in the newly born and in children. 8. The occurrence of the same tumors in the testicle. 9. The presence of only isolated, so called "organs and bones." 10. The structures are always of one side. 11. The frequent combination of these tumors with cystadenomata. 12. The so-called "parthenogenetic fetus" does not form a lithopedion.

As I have said before, the case of Dr. Jones contains too many well-defined organs to be considered a teratoma, and I see no reason why, if we judge from the report, the case is to be considered anything but an ectopic gestation, even though complicated by the presence of a cystic adenoma of the ovary. The finding of chorionic villi in the tumor would prove a definite solution, though as reported its classification seems clear.

SOME CASES OF TETANY IN INFANCY.

By JOHN LOVETT MORSE, A.M., M.D.,

of Boston.

Assistant Visiting Physician at the City Hospital and at the Infants' Hospital, Instructor in Diseases of Children, Harvard Medical School, Boston.

In 1898 I presented a paper to the American Medical Association on tetany in infancy and reported six cases. Certain conclusions were arrived at in this paper which form the basis of the statements to follow.

Tetany, like epilepsy, must be regarded merely as a nosologic entity and not as a definite disease. The only pathognomonic symptom of tetany is spontaneous, intermittent, paroxysmal, muscular contracture. The term "tetany" should be applied, therefore, only to those cases in which this symptom is present, and no cases of increased reflex excitability in which this symptom does not occur should be regarded as examples of the disease. Laryngospasm, Trousseau's symptom, Erb's symptom and the facial phenomenon are not pathognomonic of tetany and do not, either singly or in combination, afford sufficient ground for the diagnosis of this disease, because they are not constantly present in tetany and occur in many other conditions.

Etiology.—It is probable that there is no single pathologic cause for tetany, but it may arise from many causes. In improper hygienic surroundings, in rickets, in gastrointestinal diseases, in acute diseases, and in various intoxications are found conditions capable of causing the formation of various toxic substances. The action of all these poisonous substances may show itself by a special modification, rather functional than organic, of the central or peripheral nervous system. The various lesions of the nervous system which have been found in tetany are not inconsistent with this conception.

Frequency.—Griffith was able to find but 77 cases reported in American literature previous to 1894. In a careful review of American medical literature from January 1, 1894, to January 1, 1898, I was able to find but 13 additional cases, to which I added 6 of my own. In a hasty review of American literature since that time I have been able to find but few reported cases; one by Crandall in an infant, 1 by White in a child of 3½ years, 1 by Hand in a child of 3 years, 1 by Hubbard in a child of 14 months, and 2 by myself in infants of 7 and 7½ months. In 1898 the conclusion was drawn that the disease was a very unusual one in Boston. As I have seen 7 cases since that time in addition to those reported by Drs. White, Hubbard and myself, it would seem as if that conclusion was unwarranted or that the disease is becoming more common. It may be that it really is becoming more common, but it is also possible that the increase is only apparent, the condition being looked for and recognized more often than formerly.

The 7 cases are reported somewhat in detail, as they seem of interest not only as examples of the condition, but also as throwing some light on its etiology.

CASE 1.—Dominico G. was born January 13, 1900, at full term, after a rapid labor. He was fed partly on the breast and partly on condensed milk and did fairly well until the 15th of February, when he began to have 3 or 4 green movements daily. There was no vomiting. On the 19th of February he began to cry constantly. He was seen on the 20th of February by Dr. J. N. Coolidge, and the feeding regulated. At that time spasm of the hands was noted, although it had not been previously noted by the parents. I saw him with Dr. Coolidge on February 24. The digestive symptoms were almost relieved.

Physical examination. He was fairly developed and nourished. His hands and arms very often took the position characteristic of tetany. There was but little spasm associated with it, however. Neither Trousseau's nor Chvostek's symptoms were present. Kernig's symptom was absent. The reflexes were normal. The physical examination was otherwise normal.

He was seen again March 1st. The digestive symptoms were then entirely gone. His general condition was improved. The spasmodic condition of the arms was still present, but disappeared within the next 2 weeks.

In this case the cause was undoubtedly located in the digestive tract.

CASE 2.—Harry F. was bottle-fed and began to have diarrhea about the middle of July, 1899. In spite of careful feeding he continued to have a typical fermental diarrhea. There was no vomiting until October 1, after which he vomited constantly. He was admitted to the Infants' Hospital, October 12, aged 11 months, when I first saw him.

Physical examination: Small, emaciated; skin dry and covered with a papular eruption. Head flattened on top. Frontal eminences large. No teeth. Marked rosary. No craniotabes. Heart, lungs, liver, and spleen normal. Abdomen considerably enlarged.

He was fed carefully and held his weight. He did not vomit. He continued to have from 3 to 5 loose, usually yellow, movements, containing no curds, and rarely mucus, but usually very foul. With no apparent cause, the night of

Tetany in Infancy.

October 21 he began to have spasms, in which the hands and feet became rigid. They were in the position typical of tetany. Opisthotonos was present, and he cried constantly, as if in much pain. The spasms continued during October 22, and the temperature rose to 39° C. A hemorrhagic eruption appeared all over the body and extremities. Trousseau's symptom was very marked, but Chvostek's symptom was absent. The spasms continued during the night, and he died at 6 A.M., October 22.

Although there were signs of rickets in this case they were slight and evidently chronic in character, and could not well account for the acute onset of the tetany. The hemorrhages in the skin showed that there must have been marked toxic absorption. This absorption was presumably from the digestive tract, as no other organs were involved. It seems reasonable to suppose that the tetany was due to these same toxic products.

CASE 3.—Ida P. was an only child, and breast-fed. She began to refuse the breast on April 8, when 8 months old,

and developed a typical fermental diarrhea, with some vomiting. She had several convulsions on the ninth and began to cry constantly. She was admitted to the Infants' Hospital April 16th, the diarrhea, vomiting, and crying unchecked.

Physical examination: Large, fat baby. Head of normal shape. No craniotabes. No teeth. A marked rosary. Heart, lungs, liver, and spleen normal. The hands and feet were held in the typical position of tetany, with but few intermissions. Trousseau's symptom was very marked. The facial phenomenon was not present. Kernig's symptom was absent.

She was under observation for a week. She took food poorly, vomited a little, and had from 1 to 3 yellow or green movements containing mucus, but not foul, daily. The temperature ranged from normal to 40° C. She improved for 3 days, when the convulsions recurred again. Washings from the stomach and bowels at this time contained much mucus. The convulsions increased in frequency, and the spasm rarely let up. She was taken home against advice, and nothing is known as to the further history.

In this case, also, the rickets evidently had no part, the onset of the tetany being simultaneous with that of the diarrhea.

CASE 4.—Christina E. was badly fed until she was 8 months old, and had various digestive symptoms. During the next 3 months she was fed on modified milk and improved steadily. On October 13, 1899, while her digestive canal seemed in perfect condition, she began to shake her head constantly. On October 16 she had 2 convulsions, after which her cheeks swelled. Her digestion was still normal. She had another convulsion on October 18, and was first seen by me on October 19.

The general physical examination was entirely negative. There were no evidences of rickets. The hands were held intermittently in the typical position of tetany. There was no pedal spasm. The facial phenomenon was absent. Trousseau's symptom was present but not marked. Both cheeks were swollen and somewhat thickened. The gums were swollen over the lower lateral incisor teeth which had not erupted. She had one convulsion the night of October 19, but none after that. Stiffness continued in the hands until October 28. Trousseau's symptom was first absent on October 30. During all this time digestion was normal and there was no loss of weight. The swelling of the gums was the same after the relief of the tetany as in the beginning.

In this case there was no evident cause for the tetany except dentition. The swelling of the face, however, would seem to point to some toxic absorption from somewhere, although its source was not evident. It may have been in the digestive tract, although there were no symptoms of indigestion.

CASE 5.—Jacob A. was always badly fed. He began to cry constantly on October 20, 1900, and his legs and arms began to swell at the same time. There was no vomiting, and the movements were normal. He was seen October 22, when 10 months old.

Physical examination: Well developed and nourished. Head rather square and flat on top. Fontanel level. No craniotabes. Two teeth. Heart, lungs, and abdomen normal. The epiphyses at the wrists were slightly enlarged. There was a rather tense swelling of the feet and legs half way to the knee, and of the hands and lower halves of the forearms. This swelling was not hot, tender or red. It did not pit on pressure. The hands were held in the typical position of tetany. There was moderate pedal spasm. He was evidently suffering pain. Trousseau's symptom could not be tested because of the spasm. The facial phenomenon was absent. Babinski's and Kernig's signs were also absent.*

* He was admitted to the Infants' Hospital and improved rapidly. Trousseau's symptom being present during the first attacks. The swelling of the joints disappeared on the 23d. On the 24th the temperature rose to 40° C. with a face evidently due to a slight inflammation of the middle ear which disappeared after 24 hours. On October 27 the temperature suddenly rose from normal to 41° C. and the respiration to 100. Spasms of the hands and feet recurred and were followed by rigidity of the whole body. He became unconscious and died in 8 hours. Physical examination showed nothing abnormal except rigidity.

Here also, the rickets, although moderately marked, probably did not account for the symptoms. There was nothing in the digestive tract which pointed towards the absorption of toxic products from there. The swelling of the arms and legs was practically certain proof of the presence of toxic substances in the circulation. The only source for those products which was evident was the inflammation of the middle ear. It seems hardly probable, however, that this was the source.

CASE 6.—John M. was fed with great difficulty for the first 7 months. After this he did very well until March 23, when he was 14 months old. He then had influenza, as had the rest of the family. Abdominal symptoms were marked and profuse diarrhea developed. He did not do well and on March 30 the physician was discharged and he was given absent treatment by a clairvoyant. He was fed on albumen-water and beef juice. He did not vomit and had a few green movements with mucus daily. The night of April 7 he had a slight convulsion and his hands became rigid, at first intermittently and then continuously. The morning of April 8 he collapsed, and the physician was called again. He was seen that noon with Dr. W. G. Curtis, of Wollaston.

Physical examination: He was small and emaciated. The fontanel was very large. He had 8 teeth. The two lower molars were bulging the gums, which were inflamed. The tongue was fairly clean but red. The heart and lungs were normal. The abdomen was full but not tense or tender. There was no enlargement of the liver or spleen. The hands and arms were in the typical position of tetany and the feet showed a tendency to spasm. Chvostek's symptom was present. Trousseau's symptom was not tested. Kernig's symptom was absent. The patellar reflexes were not obtained. The temperature was 99° F.

It is possible that the teeth may have had some influence here in increasing the nervous excitability. The digestive disturbance, however, seems more important. It is possible, too, that the influenza may have been the first and perhaps the sole cause.

CASE 7.—Willie O.'s history was negative as to syphilis. He had been fed on various foods and never did well. He vomited off and on and was always constipated, never having a movement unaided. He began to have convulsions about the middle of February, 1900, the convulsions occurring about once a fortnight. They lasted from 1 to 10 minutes and were accompanied by frothing at the mouth, rigidity of the body and working of the hands and feet. He was admitted to the Infants' Hospital April 14, when 7 months old.

Physical examination: Fairly developed and nourished. Head normal. Fontanel large and bulging. Marked snuffles. No craniotabes. Marked rosary. Heart, lungs, liver and spleen normal. Genitals normal. No paralysis or spasm of extremities. Patellar reflexes not obtained. Kernig's symptom absent. Facial phenomenon absent. Trousseau's symptom present.

The child remained under observation about 6 weeks. During the first 3 weeks there was no improvement. He lost weight, vomited occasionally and was very constipated, the movements, however, being normal, although sometimes offensive. The temperature ranged from subnormal to 39° C. A small amount of adenoids was removed by Dr. A. Coolidge with no relief of the snuffles. He had no convulsions. The hands and feet were in the position of tetany the greater part of the time. Trousseau's symptom was always present. The facial phenomena were never obtained. He apparently suffered pain much of the time, which was increased by movement of the extremities. He whimpered all the time. At times his cry resembled that of laryngismus stridulus. Lumbar puncture was performed May 5 and a clear fluid, sterile in smears and cultures, was obtained.

There was no evidence of syphilis except the snuffles and the failure to gain. As he had not improved under other methods of treatment, inunctions of mercury were begun as a last resort. There was no improvement for about two weeks. Improvement then began and continued steadily to complete cure, not only of the tetany but of his whole general condition. The spasms had ceased by May 16 and Trousseau's symptom disappeared soon after.

The signs of rickets were slight in this case, and probably unimportant as they still remained after the cure of the tetany. The digestive symptoms may have accounted for the tetany, but the tetany was not relieved with the relief of the digestive symptoms. It was relieved completely, however, under specific treatment. The syphilis, therefore, must be considered as the probable cause of the tetany in this case.

On summing up these cases it is evident that there was no common etiologic factor. Digestive disturbances occurred in all but one. In one case they seemed the only factor. In two others they seemed the only important factor. In two more their influence could not be excluded. In one they were apparently unimportant.

Slight evidences of rickets were found in three and moderate signs of rickets in one. In no case were the signs marked. In no case were there craniotabes. In every case the signs of rickets were accompanied by other conditions capable of causing tetany. The absence of craniotabes and the slight degree of the other rachitic changes confirm the opinion that craniotabes is not a cause of tetany and that rickets is not a direct cause of tetany. Rickets probably acts only indirectly by weakening the resistance of the nervous system or may be merely a result of the same case as the tetany.

In two cases the gums were distended by teeth. In one of these no other cause of tetany was evident. The gums were in the same condition, however, after recovery. In the other case influenza and diarrhea were also possible etiologic factors. It does not seem possible, therefore, that difficult dentition alone can cause tetany. It may favor its development, however, by exaggerating the excitability of the nervous system.

Influenza seemed the possible cause in one case. Syphilis was apparently the cause in one case, as recovery did not take place until after the use of specific treatment, the tetany not improving when all the other conditions except the syphilis were relieved.

In every case but one, conditions were present evidently capable of causing toxic products. In this case also it is impossible to exclude some such condition, possibly digestive. Absorption of these toxic products into the circulation, with the resulting action on the nervous system, seems to offer the most reasonable explanation as to the cause of the disease. It is evident, too, that these toxic substances may be of various sorts and the results of many varied conditions. The conclusion seems warranted, therefore, that tetany is due to the action of the toxic products of many diseased conditions on the nervous system.

Treatment.—As tetany is almost certainly due to the action of toxic substances on the nervous system, treatment must be directed to the cure of the primary disease, to the prevention of the formation of toxic products, and to their elimination, if already formed. Symptomatic treatment to relieve the pain and discomfort is also important. It is not curative, however, and must never be used to the neglect of the treatment of the causative condition.

Tuberculosis in Germany.—Of the 1,120,000 deaths recorded in the German empire in 1899, 110,200 were caused by tuberculosis.

THE RELATION OF STATE AND LOCAL BOARDS OF HEALTH TO OUTBREAKS OF DIPHTHERIA.*

By G. E. TYLER, M.D.,
of Denver, Col.

Secretary of Colorado State Board of Health.

THE presence of one case of genuine diphtheria in a community is an occurrence of sufficient importance to demand the earnest attention of those responsible for the prevention of the unnecessary spread of disease. For a single mild case may mean many severe ones and the death of not a few individuals. If Pasteur's now famous aphorism, "It is in the power of man to cause all parasitic diseases to disappear from the world," be true, there is need of greater ability in applying our present knowledge concerning this one. As diphtheria is a disease for which there exists a positive method of diagnosis and a specific treatment, Pasteur's prophecy ought to have a fair testing in its management. It is my purpose to attempt to set forth the methods to be used by health officials in their battle with this disease.

There should, at all times and in all places, be offered competent bacteriologic facilities free of charge to every citizen. The absolute uncertainty of clinical phenomena for mild or atypical cases has been repeatedly proved. The throat may present but the faintest hyperemia, yet the culture may be positive. In well-marked cases the clinical appearances are sufficiently distinct to warrant a positive diagnosis without the aid of a bacteriologist, but it cannot be too strongly emphasized that the greatest skill in clinical work is not sufficient to detect mild cases of genuine diphtheria. Because of this fact no obstacle should be placed in the way of obtaining a prompt bacteriologic diagnosis. On the contrary, every facility should be offered the interested person, whether he be a physician or an anxious parent. Culture outfits in convenient form should be placed at accessible supply depots, each outfit being accompanied by plain printed instructions as to the method of use. In cities messengers should be provided to collect the outfits as soon as the cultures have been taken. Whenever requested, an officer of the local board of health should be sent to take the culture. In small communities it is quite out of the question to maintain a bacteriologic laboratory. It then becomes the duty of the State Board of Health to supplement the work of the local board by furnishing the necessary facilities. To accomplish this, the State Board of Health must have a competent bacteriologist, not appointed for political reasons. It must also provide all incorporated towns which have no local laboratory with culture outfits, and there must be prompt communication between the supply depots and the laboratory. The culture outfits should be as complete as possible, in order that the cost of sending them may be reduced to the minimum. The former regulations of the Post Office Department required a clumsy outfit which was poorly adapted to the work, and which required 12 cents postage every time it was mailed. Through the efforts of the Colorado State Board of Health, assisted by others interested, the regulations were so modified as to permit the use of a much smaller outfit. It was formerly the custom to treat these specimens as fourth-class mail, but the new order directs that they be treated as letter mail. This may mean a difference of 12 hours in the receipt of the specimen. Every State Board of Health should be granted sufficient funds to establish these supply depots. The State Board

of Health of Colorado had such depots established in every county about September 1, 1900. The service of the laboratory is free of charge to every citizen and reports are made as promptly as possible. In every positive case immediate report will be made by telegraph. A like prompt report will be made in negative cases when requested. In sending specimens the name of the patient should be given as well as that of the person sending the specimen.

Physicians should take cultures in every case which looks at all suspicious. Much tact is required to secure the active participation of some in this movement, but the wise health officer will so protect the interests of the profession that all, except the few who are by habit opposed to everything, will see the advantage to be gained by frequent use of the laboratory.

Free antitoxin should be provided for all infected individuals who cannot afford to buy it. The early use of antitoxin is of such extreme importance to the successful management of diphtheria that physicians should be given to understand that whenever they have a case which demands it, antitoxin sufficient for the patient can be had for the asking. As the State Board of Health has no funds for such purpose, local boards must supply this.

Every case of diphtheria should be reported to the health authorities and a record of it be made by them. Physicians outside the large cities of Colorado do not seem to know that the law requires immediate report of all cases of contagious disease, but they have usually been willing to make such reports when informed of the law. The State Board of Health furnishes blanks for such reports free of charge, and is seeking to make complete and accurate record of all cases. The record made by the health authorities should show the exact location of the patient, the number and names of the rest of the family, and all others known to have been exposed. The local boards should make note of the milk, water, and ice supply, and, if there are children in the family, the school and Sunday-school should be recorded. The officers of such schools should have early notification of the existence of the disease, the public librarian should be notified in order to see whether any books are in the family, and care should be exercised to prevent the spread to other families by the milk-supply. For the protection of the public, every house in which diphtheria is present should be distinctly placarded. Some have questioned the necessity of the placard, but every person visiting a house has a right to know before he enters whether he will encounter diphtheria by entering. If every infected house is placarded without favor to rich or poor, the community will appreciate the value and justice of the regulation. The regular notification of public school and Sunday-school officers does much to educate public sentiment. Furthermore, the record of such data often enables the intelligent health officer to trace the different cases to a common source.

The great value of keeping record of the milk-supply has been demonstrated many times.

The question of quarantine is important. Who shall be quarantined, and for how long? The patient must be quarantined until his throat is free from bacilli. This seldom occurs under 3 weeks, and because people grow restive under repeated positive reports it is wise to fix the minimum period of quarantine at 3 weeks, and to take no secondary cultures during this time. The Colorado State Board of Health has adopted the following rule:

* Read before the Colorado State Medical Society, June 21, 1900.

"In all cases where the bacteriologist reports the diphtheria bacilli present, the patient should be absolutely quarantined. A second culture should be taken 21 days after the first and forwarded for examination. Quarantine must be maintained until the bacteriologist reports the throat free from diphtheria bacilli. No children from the family should be allowed to attend school until 2 weeks after the throat is free from diphtheria bacilli."

The breadwinners need not be kept from their work, unless they be school teachers, or others who mingle much with children, but they should be cautioned to be little in the sick-room, or else to be careful to change their clothing and bathe with antiseptics before leaving the house. Before a nurse employed in a diphtheria case goes to another patient a culture from her throat should be examined and her clothing should be disinfected. In fatal cases of diphtheria the funeral should be private and under the supervision of a health officer.

Those exposed should be given immunizing doses of antitoxin, and this should be repeated in two weeks if exposure continues. With the present state of public opinion, it is not wise for health officers to insist upon immunization of the exposed, but they should do all in their power to encourage it. Some day the custom of immunization after exposure to diphtheria will be as common as vaccination after exposure to smallpox.

The State or local board of health should have circulars for public distribution, and one of these should be placed in the hands of the head of the family where the disease appears. The following is from a circular on this subject issued by the Colorado State Board of Health, it being identical with one previously issued by the Denver Bureau of Health:

"Diphtheria is a disease which manifests itself especially in the throat. It is so dangerous and so difficult of identification, that every sore throat should be regarded as suspicious, and the person suffering from it kept out of school until the throat has been examined by a competent person and the nature of the sickness determined. The State Board of Health determines absolutely the existence or nonexistence of diphtheria by a bacteriologic examination of the secretion from the throat, and this examination is made at the request of any citizen without charge. Children from houses in which diphtheria has occurred should not be allowed to resume school attendance until 2 weeks after a bacteriologic examination has shown the throat of the sick person to be free from diphtheria germs, as certified by the health authorities."

Toys with which the sick child has played should be destroyed or soaked in a strong antiseptic. Books should be burned and all articles which will stand it should be separately boiled. The necessity for thorough fumigation is apparent. For disinfection of the room the Colorado State Board of Health recommends five pounds of sulphur to each 1,000 cubic feet of space with exposure for twelve hours; or formaldehyd sprinkling, using five ounces of the 40% solution for each 1,000 cubic feet of space. The objection to the former is its corrosive action and to the latter its poor penetration.

The constant use of the bacteriologic test, the prompt application of the serum treatment, complete isolation of infected individuals, immunization of all exposed, and thorough disinfection—these are the methods which intelligently applied will prove the truth of Pasteur's aphorism.

Courtenay C. Parsons, M.R.C.S., L.R.C.P., Civil Surgeon South African Field Force, died of enteric fever in Harrismith, on December 2.

Surgery of the Pleura and Lung.—H. Verneuil (*Annales de la Société Belge de Chirurgie*, 1900, 18me Année, p. 121) gives an interesting review of this subject. He finds that many affections of the pleura and lung formerly considered incurable are now greatly benefited by surgical intervention. He mentions particularly empyema, traumatic lesions, tumors of the lung and pleura, and encysted collections within the lung, particularly abscess. The diagnosis in these conditions is usually difficult. Percussion and auscultation, which are often sufficient for medical diagnosis, are too incomplete to locate accurately intrapleural lesions for surgical intervention. Exploratory puncture often gives valuable information; in case fluid is found it permits bacteriologic examination and makes diagnosis possible in many cases of hydatid cysts, collection of blood, tuberculosis, or cancerous pleurisy. The character of the expectoration is of some importance, but in many cases the expectoration is moderate in amount from a very large cavity, while with a small cavity there is abundant expectoration. In cases of doubt, exploratory operation is many times justifiable with direct palpation of the lung either through the pleura or after opening the pleura. But the information obtained even by exploratory operation is sometimes uncertain. Verneuil considers the x-rays among the most important and precise means of diagnosis and he believes that the importance of their use is increasing. In many doubtful cases where it is impossible to make a diagnosis by auscultation and percussion and exploratory puncture the x-rays have given exact information. In case of injury to lungs and pleura, hemorrhage and the presence of pneumothorax are the indications for operative intervention, but the determination of the time when that intervention is desirable is often very difficult. Very often the patient is in an extremely bad condition, almost livid, the pulse small, and there are signs of a large effusion. It is not uncommon, however, to find that the condition of these patients is completely transformed 24 hours later. The amount of blood constituting the hemothorax is not decreased, but the pulse is better, the general condition improved, the dyspnea entirely disappeared and a perfect recovery results without operative treatment. Operations undertaken under these conditions offer very few chances of success when one considers the intense traumatic shock and usually the imperfect preparations for intervention. Operation is considered justifiable only when there is the conviction that hemorrhage is continuing either from the thoracic wall or from the lung. In such cases a wound in the lung may be sutured or an injured intercostal vessel may be ligated successfully very frequently. The tamponing of the pleural cavity, it is thought, should be abandoned. Timid intervention is condemned as a result of much observation. Once the operation has been decided upon it should be extensive. In many cases of empyema it is believed that Estlander's operation should be resorted to earlier than is now generally the case. If it is found that after sufficient drainage for a reasonable length of time improvement does not result, costal resection should not be delayed. In the case of an old empyema Schede's or Delorme's operations are frequently indicated. Primary tumors of the lung with the exception of hydatid cysts and actinomycosis are extremely rare. Primary cancer of the pleura or lung is rarely recognized in an early stage and later on it is inoperable. Actinomycosis has been successfully treated by thoracotomy and resection of the lung. Hydatid cysts are best treated by incision, disinfecting, and packing. In cases of abscess of the lung, bronchiectasis or gangrene of the lung, drainage will be necessary. The simplest forms of drainage are usually the best. Puncture is rarely sufficient in case of abscess of the lung. Some favor the turning back of an osteoplastic flap, others costal resection. Verneuil considers the latter the preferable method of operation in most cases. In operating for bronchiectasis the results will be more favorable, the nearer the condition approaches that of pulmonary abscess. Some surgeons advocate the maintenance of a bronchial fistula. Pneumonotomy in pulmonary gangrene has not given very encouraging results. If the patient recovers from the immediate effects of the condition the later results seem more encouraging. Pneumopexy is advocated in cases in which there is not adherence of the parietal pleura as a means of avoiding the dangers of pneumothorax. Except in very rare cases, surgical intervention is not considered justifiable. [M.B.T.]

Parasitic Hemoptysis in the United States.—The Marine-Hospital Service calls the attention of health officers and physicians to the important fact that the United States Bureau of Animal Industry has found more than 50 cases of infection in hogs by a lung fluke known as *Paragonimus westermanii*. Heretofore, this parasite has been observed but rarely in America, although it is quite common in some parts of China and Japan, and possibly in the Philippines. Drs. Stiles and Hassall are about issuing a report of their investigations, from advance proofs of which the following facts are gleaned. This parasite was originally described by Kerbert (1878) in the tiger, by Manson (1880) and Baily (1880) in man, by Railliet (1890) in the dog, and more recently by others in the cat. A full zoological description of the paragonimus is given by the authors, from which we learn that it is a fluke worm, 8 to 16 mm. long, 4 to 8 mm. broad, and 2 to 5 mm. thick. It is found encysted, usually two individuals in each cyst, with eggs, and its habitat is the lungs of mammals. It seems to be identical as observed in the various mammals—tiger, dog, hog, cat, and man—in which it has thus far been found. Its life history is still very obscure. According to Stiles and Hassall the complete life cycle of the lung fluke has not yet been experimentally demonstrated. It seems clear that the egg does not develop until it leaves the host in the sputum. Manson and Nakahama each succeeded in hatching the eggs in warm water, but the natural environment is yet unknown. Beyond this miracidium stage nothing is positively known, but the presence of cilia indicates an aquatic life, and all analogy points to the probability of some intermediary host. Certain of the invertebrates, such as the mollusks (snails, etc.), have been under suspicion; as have also chickens and their eggs, for chickens are well known to eat human sputum. This whole subject of the life history of the *Paragonimus westermanii* is discussed in detail by the authors.

The symptoms of parasitic hemoptysis vary according to the location of the parasite. The lung infection is the usual form. Spitting of blood is common. A sputum, very similar to that of pneumonia, and of a dirty red or brown color, due to the presence of eggs of the worm, is raised during the intervals between the hemorrhages. The only constant and specific characteristic is the presence of the eggs in the sputum. As

many as 12,000 eggs may be expectorated daily. The brain also may be infected. Epileptiform attacks, of a Jacksonian or cortical type, result. These and other brain symptoms are caused by the presence of the worm or its eggs, or from emboli in the arteries. The liver and other organs also may be involved.

Drs. Stiles and Hassall state that two cases of this disease were recorded in the United States in 1894 and 1895; one in a cat in Michigan and the other in a dog in Ohio. It was hoped that the infection would not spread, but this hope has been disappointed, for the meat inspectors of the Bureau of Animal Industry, stationed at Cincinnati, have, on repeated occasions, discovered lesions in hogs which Stiles and Hassall have determined were due to the presence of this parasite. The worms collected from hogs in Cincinnati are identical with those found by Manson in man. Dr. Stiles thinks the parasite has been introduced into this country from China or Japan, and he fears that our troops returning from the East will add to the infection already here by bringing sporadic cases of the disease with them. Treatment so far is inefficacious, although patients may live for many years.

Science Between the Acts.—A report comes from Paris that Dr. Hanriot, of the Academy of Medicine and the Board of Health, is creating a sensation among theater goers, as well as consternation among theater managers in that city, by a series of experiments undertaken to prove that the air of Paris theaters is loaded with microbes. When these experiments were begun last winter, the preliminary results were so alarming that the French Government interfered for fear of their injurious effects upon the approaching exposition as well as upon the theaters. So paternal is the Republic over there that it even controls the ventilation of the theaters and the distribution of bacteria. Now that the exposition is a thing of the past, Dr. Hanriot is once more at work. His method is rather sensational, as becomes the atmosphere of Paris. He arrives in the midst of a performance and settles himself in a box with his apparatus and assistants. As the apparatus makes a loud buzzing noise he graciously sets it going only during the intervals between the acts. He and his assistants then talk in a loud tone in order to drown the noise of the machine. The immediate effect on the audience is not described; but the scientific results,

as announced by Dr. Hanriot, are important. He says that the air of some of the Paris theaters is "little better than dusting." His recommendations are for better ventilation and for the substitution of leather for plush upholstery. This latter point seems to be one of great importance, for Hanriot's observations go to show that those theaters which are upholstered in plush are the most infected.

Cystitis Typhosa.—The elimination of typhoid bacilli through the kidneys has been known for a long time. Smith and Gwyn in this country have made some very interesting studies in regard to the possibility of the dissemination of the disease by this method, although the earliest statements on the subject date from Konja-jeff and J. Neumann, and since their publication in 1889 the subject has excited considerable interest on the part of various investigators, such as Petruschki and Curschmann. Lately the latter has again taken up this subject,¹ and draws a sharp distinction between the mere presence of the typhoid bacilli in the urine, eliminated by the kidneys without harm to the individual, and the existence of a true inflammation of the mucous membranes of the bladder, produced by the action of the microorganisms. To the latter he gives the name "cystitis typhosa." This condition is, comparatively speaking, rare, in view of the fact that in anywhere from 6 to 100% of all cases of typhoid fever examined by different investigators, typhoid bacilli were present in the urine, and as the number of cases hitherto examined exceeds 1,000, and the average percentage is about 30, the frequency with which typhoid bacilli are found in the urine is extraordinarily great. Curschmann has had an opportunity of studying 3 cases in which the ordinary symptoms of cystitis were present; that is to say, large quantities of pus-cells were found in the urine together with typhoid bacilli, whose nature was proved by cultural peculiarities, and their reaction to typhoid blood. The curious features about these forms of cystitis are the acid reaction of the urine, the absence of epithelium from the kidneys, or the renal pelvis, and the absence of any true signs of nephritis, although in the early stages of the disease, a transient albuminuria, probably febrile in character, is present. In the first case, an interesting feature was the presence of virulent bacilli in the urine after the cystitis had completely healed. The third case showed certain peculiarities. The inflammatory process lasted more than 4 months, and was finally cured by injections of a solution of silver nitrate, followed by the complete disappearance of the typhoid bacilli or, rather, their replacement by the colon bacilli. Curschmann calls attention to a few of the characteristics of this disease. It can only develop after an attack of typhoid fever, of course after a bacteriuria has occurred. Why this bacteriuria produces

cystitis in such a small proportion of all the cases, it is difficult to say, for the disease occurs in perfectly healthy, vigorous individuals as well as in the aged. The subjective symptoms are very slight. The patients complain of practically no pain, and do not have dysuria, excepting in rare cases. There is no febrile elevation of the temperature; the urine has an acid reaction, is cloudy and contains the bacteria and pus. The disease does not extend to the ureters, nor to the kidneys. The course is variable; usually brief, but it may be exceedingly chronic. The prognosis is favorable in all respects, and the treatment consists of the administration of salol, lavage of the bladder with a solution of silver nitrate, or the administration of urotropin. (Horton Smith's method.) All these measures are also useful in overcoming the simple bacteriuria. The chief feature about this condition is of course the fact that on account of the absence of subjective symptoms, the condition may be overlooked, particularly as it often occurs after convalescence is well started, and there is no apparent reason for continued examination of the urine. The possibility of the dissemination of the disease by this method has already been insisted upon by Gwyn in these columns.

Influenza and Hay Fever.—The prevailing epidemic of mild influenza revives, even in midwinter, the perennial subject of hay fever. Some persons think they have made the discovery that the two diseases are in a sense antagonistic; or, at least, that the victims of hay fever are not so prone to the grip as are the rest of the world. This fact, if true, would seem to indicate that hay fever, as well as influenza, is a disease of microbic origin, and that the infecting organism of the one has the power of rendering its victim immune to the action of the other.

The theory that hay fever is a neurosis is perhaps not well based on the observation of facts, and is likely to succumb to the all-dominant microbe. It would perhaps be more reasonable to claim, as Dr. A. O. J. Kelly has done in the case of arthritis deformans, that it is an infectious trophoneurosis. The fact is well established that the disease is curiously under the influence of mental impression, and is sometimes controllable by agencies that control the pure neuroses. This has been well demonstrated in this city in recent years by a man of independent means, who was himself a victim of hay fever. After traveling every year to different resorts in a vain search for relief, he determined at last to fight it out in his city house, where he could at least have the comforts of home. He accordingly returned every August to his city house and locked himself in. Strange to say, the customary attack was averted. This experiment has proved absolutely successful now for three years in succession. Such a case, it may be thought, only goes to prove the truth of the pollen theory—a theory which was so elaborately

¹ *Munchener med. Wochenschrift*, October 16, 1900.

worked out by Blackley in England in 1866-78. And yet pollen is probably not absent from the air of cities.

If a genuine antagonism could be demonstrated between hay fever and influenza, it would be interesting to note what use the bacteriologists could make of the fact in the way of establishing a prophylaxis.

A New Treatment for Tuberculosis.—From the standpoint of its pathology the ideal method for the cure of tuberculosis would be to render the lungs aseptic. Taking into consideration the nature of the air-passages and their constant exposure to the bacteria-laden atmosphere, this is manifestly impossible, at least if attempted by the inhalation of vapors containing antiseptic substances. Maguire (*British Medical Journal*, December 15, 1900) proposes to employ the blood-vessels to render the lungs aseptic. After experimenting with cyanide of mercury, iodide of potassium, perchloride of mercury, diastase, and nuclein, he decided that formic aldehyd was the most likely to prove of use as a germicide that could be injected into the peripheral veins, and that would pass thence to the lung through the pulmonary artery, diluted only by the contents of the right ventricle. He found that a solution of one part pure formic aldehyd gas in 2,000 parts of normal salt-solution could be employed with safety and that he could inject 2 cc. in the space of 5 heart-beats. He calculated that by this process in the space of 5 heart-beats, the lung would be washed out with a 1:500,000 solution of formic aldehyd. Still further attempts developed a manner of using a more rapid process of injection and for a longer time, so that he now believes that he can sluice the lungs during a considerable number of heart-beats with a 1:50,000 solution. For the injection he employs a buret at the lower end of which is a soft rubber tube bearing a hypodermic needle of large caliber. A bulb, similar to the one used on the Pacquelin cautery, is attached to the upper end of the buret by a cork. The patient's arm is ligated as for venesection and under aseptic precautions, the needle is plunged boldly into a vein, the ligature loosened and the tap of the buret turned. He advises that not more than 50 cc. of the 1:2,000 solution be injected daily. Larger quantities which he had the hardihood to inject into his own system caused albuminuria, copious hematuria, and finally thrombosis of a vein in the arm. As a result of this treatment cough is generally increased and the expectoration becomes more frothy and mucous. Of 70 patients who have been submitted to this method of pulmonary aseptis, nearly all showed some improvement and in some there has been demonstrated absolute disappearance of tubercle bacilli from the sputum. It seems to us that the treatment suggested is, to say the least, heroic. Making due allowance for the strength of the solution, the action of formic aldehyd on the organs after they have been removed from the body should be borne in mind. It

would seem reasonable to fear that after the continued use of a weak solution even, a cirrhotic process might be induced in some of the other viscera, if not in the lungs, thereby setting up a second serious disease while curing the primary lesion. It would seem wise, before this method is generally employed, to study carefully the action of such a solution of formic aldehyd on the red blood-corpuscles outside the body; because it does not seem out of the range of possibility that long exposure to such a solution might seriously harden the stroma of the cells and thus interfere with their oxygen-carrying power.

The Plague in Manila.—The state of health in our recently acquired Philippine Islands is a subject of special interest now to all American physicians. The Government has new problems to face both in hygiene and in practice. It thus happens that the recent report of Surgeon-General Sternberg on the prevalence of plague in Manila brings home to us a topic of great moment from several standpoints. We are not only interested in plague as it has prevailed in Manila, but also as it may possibly be imported into the United States from that center of infection. The pest made its first appearance in Manila in December, 1899, little more than one year ago. The first cases were reported as instances of typhoid fever. One death occurred in December, 11 in January, 35 in February, 49 in March, 44 in April, 17 in May, and 11 in June, while during each of these months from 40 to 80 Chinese died from causes unknown, they having been without medical attendance. The reported cases all told numbered 225 of which only 58 recovered. It thus appears that there was a well-established epidemic of the disease in the city of Manila.

Only two white men contracted the disease and only one American died of it—an employe of the quartermaster's department. The epidemic was confined almost exclusively to the native and Chinese population. It is reassuring, in this connection, to read Surgeon G. L. Edie's confidently expressed opinion that but little difficulty will be experienced in controlling the disease in any intelligent community with modern sanitary methods. This opinion is hardly sustained by experience with plague in other quarters of the globe, and yet Dr. Edie, who is the Health Officer in Manila, had ample opportunity to form an opinion in this epidemic. That he can come to such a conclusion after combating plague in an Asiatic community, is certainly noteworthy. He speaks highly of the intelligent and efficient help rendered by the Chinese. The prompt detection of cases among these people was largely due to the vigilance of the Chinese Consul and the Chinese merchants. The latter furnished 40 inspectors [from their own number, and contributed funds for] building and maintaining a pesthouse. The Filipinos also were pressed into service as inspectors and did efficient

work. The disease was combated in a thoroughly scientific way—such as usually characterizes the Government's medical work. But Dr. Edie says that he and his assistants were not favorably impressed with either Haffkine's prophylactic or Yersin's serum, but he acknowledges at the same time that a thorough test had hardly been given to either. He says it is almost impossible to use them on the Chinese or natives without resorting to force.

The Essential Nature of Whooping-cough.—The efforts to determine the nature of whooping-cough, and its etiology, began with the first reported appearance of cases of the malady early in the sixteenth century. Its contagious character was made manifest by the great epidemics which spread over Europe during the latter part of this period. Many theories have been offered in explanation of the condition, and in many instances these have been utterly irreconcilable. However, it is interesting to take careful notice of the evolution of medical opinion. We must not dismiss old dogmas with a wave of the hand, but with careful judicial mind must sift out these theories, and glean whatever of truth there is in them. It is well to remember that medical thought advances in cycles, and too often we have discarded as valueless what has subsequently been readopted, after, perhaps, years of vain groping, and found to contain the essentials of truth.

The prevailing humoral theory of the eighteenth century sought to attribute spasmodic seizures to digestive disturbances, and explain the symptoms by an irritating action exerted upon the diaphragm and the respiratory organs. It was Linnæus, the botanist, nearly two hundred years ago, who attributed the condition to the inhalation of a *contagium animatum*. We find that by many the disease has been regarded as a simple bronchitis, of a form involving mainly the finer bronchioles and the alveoli. (Broussais and Desruelles, 1824.) Löschner (1868) held the same view, but explained the spasms of coughing by the reflex irritation caused by the decomposing secretion. Beau advanced the theory that a mechanical irritation of the larynx was sufficient to produce the symptoms, and held that inflammation of the laryngeal mucous membrane was the cause. In 1870, Letzerich promulgated the theory of the inhalation of spores, and believed that upon their multiplication the seizures could be brought about. Canstatt and Lebert held that the disease is of zymotic origin, affecting the general system, and that the paroxysms only indicate the respiratory system was most involved. This theory was advanced, on account of the frequent concurrence of measles with whooping-cough. Henoch, among others, gives force to the theory that pertussis is a neurosis, affecting the respiratory nerves and the sympathetic system. He reminds us of the aura which is present, in the fact of the child's anticipating the attacks. He concedes the catarrhal condition of the mu-

cous membrane present, but gives an important place to the nervous element of the disease, as indicated by the spasmodic violence of the expirations, by the apnea, and the crowing sound of spasmus glottidis. He calls particular attention to the fact that in many cases the vomiting is the major symptom, and the cough but slight in intensity, and further states that it is an open question whether the reflex irritability of the medulla acting through the vagus is to be blamed here.

As to the pathologic condition, it may be stated that the characteristic lesions found in an uncomplicated case of whooping-cough are a catarrhal inflammation of the respiratory mucous membrane, which, according to von Herff and Myer-Hünn, is most severe in the nose, larynx, and trachea, although it may extend into the small tubes. In certain cases, however, Rossbach has found all the parts of the trachea and larynx normal. Rehn found the anterior laryngeal wall to be the portion most involved, while others held the opinion that the posterior wall of the antihyarytenoid region seems so be the general focus. The constant occurrence as laid down by Beau and Gendrin of catarrhal inflammation at the entrance of the larynx, has been proven to be too broad a statement. It appears that in most of the cases the catarrhal inflammation is found in the infraglottic region, but so varied is the description of the localized point of inflammation that it would seem reasonable to assume that the site of the inflammation is dependent upon the locus minoræ resistantiæ of the membrane. In the majority of cases the larynx is involved, or the bronchial tubes at their bifurcation. It is quite generally conceded that pertussis is an infectious disease, and bacteriologists have been energetic in their efforts to isolate the specific microorganisms. The names of Deichler (1886), Cohn and Newman (1895), Kurloff (1896), Czapslewski and Hensel, Ritter and Afanasieff and, finally, Koplik are foremost among those who claim to have isolated the specific cause. The manifold complications of the condition are perhaps exceeded by no other disease. Bronchopneumonia, emphysema, tuberculosis, and measles are especially important. We find the inflammation of the bronchial glands a very constant feature, and many have assigned to them etiologic importance. The most acceptable explanation of this condition, however, is that it is a sequela and due to the accompanying catarrh of the mucous membranes. The leukocytosis, which so constantly is present in whooping-cough, affects especially the lymphocytes, but we must not forget that lymphocytosis is common in other conditions in childhood. It would seem a reasonable explanation, at least in part, to concede that the specific organisms having gained entrance, upon some favorable site elaborate a toxin, and that this toxin, being absorbed and accumulating in virility, acts particularly upon the superior laryngeal and vagus nerves. The fact must finally be borne in mind that the postmortem

lesions found, both of the nervous and general system, vary widely, and that we are forced to regard them as complications rather than a part of the specific process. There is unquestionably an infectious agent present with its point of secretion in the respiratory mucous membrane, and that an intoxication is produced, as the disease progresses, would seem borne out by the burden of proof.

A New Medical Journal.—We extend a cordial welcome to the *New York State Journal of Medicine*, the first number of which lies before us. The new journal is the official organ of the New York State Medical Association, and will appear monthly. Its initial number is highly creditable, and its succeeding numbers we doubt not will be still better. In the announcement, its editor, Dr. J. H. Burtenshaw, says that the new enterprise marks a distinct era in the affairs of a State medical organization. We must call his attention in this connection to the fact that the Pennsylvania State Medical Society has long had an official organ in the excellent *Pennsylvania Medical Journal*.

Correspondence.

THE COMMON FLY AS A FACTOR IN THE TRANSMISSION OF DISEASED GERMS.

By JOSEPH LEIDY, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

It has occasioned no little surprise to the writer that while the profession and laity have shown a natural interest in the relation which the mosquito (*Anopheles quadrimaculatus*) bears to the etiology of malaria as the host through which the germ finds its way into man, so little attention has been given to the relation which the common fly holds as a factor in the transmission of disease.

The writer has taken the opportunity of examining the contents of the stomach and proboscis of a number of flies caught at random in the reception ward of the Pennsylvania Hospital, and of a number which have been allowed to feed upon the discharge from suppurating wounds, surgical dressings, fresh and dried blood preparations, and various kinds of decomposing vegetable and animal matter.

The results obtained from a series of experiments in this direction suggest interesting problems, and firmly convince the writer that the fly may become an important factor in the transmission of diseased germs.

This preliminary note is made for the purpose of calling your attention at this time to a pest which it would not be wise to overlook while we are making our attack upon the *anopheles*.

In the Proceedings of the Academy of Natural Sciences, Philadelphia, 1871: "Professor Leidy remarked at this time (during the prevalence of smallpox) he was reminded of an opinion he had entertained that flies were probably a means of communicating contagious diseases to a greater degree than was generally suspected. From what he had observed in one of the large military hospitals, in which hospital gangrene had

existed during the late rebellion, he thought flies should be carefully excluded from wounds. Recently he had noticed some flies greedily sipping the diffuent matter of some fungi of the *Phallus impudicus*.

"He caught several and found that on holding them by the wings they would exude two or three drops of fluid from the proboscis, which examined by the microscope were found to swarm with the spores of the fungus. The stomach was likewise filled with the same liquid, swarming with spores."

PREVENTION OF TUBERCULOSIS.

By P. A. SHEAFF, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

MEASURES for the prevention of tuberculosis is a subject that justly calls for consideration and thought, not only on the part of the medical profession, but by every one interested in their own or others' welfare.

Not until the public at large becomes acquainted with the facts in regard to the care and necessity of properly disposing of tubercular sputum, and heeding the same, can efforts in this direction prove of much avail.

Efforts instituted for the prevention of a disease so widely distributed and affecting so many persons should receive the consideration of every right-minded individual, and with all due respect and reverence to religious teachings and customs may I call attention to the prevailing method in regard to the passage of the communion cup in vogue in many of our churches?

True it is that some congregations have adopted the individual-cup method; but are they many, compared to those who have not?

Is it man's moral and religious duty to knowingly place himself in a position where he may be the means of infecting others or becoming infected himself?

It is not in condemnation of the performance of this most solemn religious rite that I speak, but in observance of the same in a manner that would accord with hygienic teaching.

Teaching Anatomy.—Shepherd (*The Montreal Medical Journal*, November, 1900) insists on the oft-repeated statement that the dissecting-room is the place for the medical student to learn anatomy. The lecture is little more than a demonstration; and its retention is the survival of a method in vogue when subjects were obtained only with difficulty and at long intervals. Morphology, however interesting and instructive, has small place in the crowded course in anatomy. Osteology, the anatomy of the nervous system and the viscera, are the most important. During recent years the anatomy of the lymphatics has increased in importance, and that of the bloodvessels has decreased, except from a purely surgical standpoint. The author questions the wisdom of teaching histology in a separate course from anatomy and physiology. He says as a teacher he is daily amazed at the small amount of anatomy retained by the average fourth-year man, and even by those who did well in their second-year examination. Attention is called to the fact that the present-day teacher of anatomy is too much specialized, and that the student should be taught the practical points and these insisted upon. [From the tone of the author's address it is exceedingly doubtful whether he would favor placing the whole course of anatomy in the student's first year, as is now being done by a few schools. A.B.C.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. H. C. Catell Resigns.—Dr. Henry C. Catell, pathologist to the Pennsylvania Hospital, has resigned.

Dr. Anselme Walker, of Freehold, New Jersey, died January 6, from pneumonia. He was one of the founders of the New York Pharmaceutical Association.

Antiseptic Telephoning.—A Philadelphia firm is putting upon the market an antiseptic mouth piece for telephones. The contrivance has been adopted by several corporations.

Dr. John M. Brister, who left on Monday for the Mare Island Navy Yard, where he was assigned as assistant surgeon, United States Navy, was given a farewell dinner on Saturday evening at the home of his brother, Dr. F. Elmer Brister.

Nurses Graduate at Philadelphia Hospital.—The graduating class for the Training School of Nurses at the Philadelphia Hospital, comprising 13 nurses, received their diplomas. This makes the sixteenth anniversary of the Training School.

A Practitioner of High Standing Dead.—Dr. D. R. Bardin died of Bright's disease, at Avondale. He had been practising since 1866. Dr. Bardin was born in Dalton, Mass., February 10, 1820. In 1842 he graduated from the New York University. He obtained his medical degree in 1856. The deceased will be buried in Woodland Cemetery.

Death of a Famous Army Nurse.—Mrs. Anna Morris Holstein, who had obtained considerable fame as an army nurse, died at her home at Red Hill, near Norristown, Pa., at the age of 76. She was matron-in-chief of a hospital in which there were 3,000 seriously wounded after the battle of Gettysburg. She was instrumental in the purchasing of the army headquarters of Washington at Valley Forge.

Physicians Choose Officers.—At the meeting of the College of Physicians held last evening, the following physicians were elected officers: W. W. Keen (reelected), president; H. C. Wood, vice-president; William F. Norris, R. A. Cleemann, Arthur V. Meigs, and S. Weir Mitchell, censors; Thomas R. Neilson, secretary; Richard H. Harte, treasurer; Frederick A. Taggart and Elliston J. Morris, councillors.

Death of Dr. Richard Linderman.—We regret to announce the death of Dr. Richard Johnson Linderman, in this city, who was not only well known in his profession, but who represented Bucks County in the State Senate from 1869 until 1870. He had been ill for 3 years with cardiac disease. He was president, until about 20 years ago, of the Quaker Town City Bank, and also connected with various other public as well as medical associations.

Cooper Hospital Physicians.—At the annual meeting of the trustees of the Cooper Hospital the following were elected as the visiting staff of physicians and surgeons: Medical—Drs. W. A. Davis, E. L. P. Godfrey, W. R. Powell; surgeons—Drs. Daniel Strock, Joseph Nicholson, Paul M. Mearay, and E. A. Y. Schellinger; ophthalmologist—Dr. W. R. Powell; gynecologists—Drs. Dowling Benjamin and J. S. Baer; laryngologist—Dr. E. S. Ramsdell; pathologist—Dr. S. Bray.

Course in Neuropathology.—An elective course in neuropathology has been opened in the University of Pennsylvania by Dr. W. G. Spiller, who has recently been appointed demonstrator of that branch. The course is open to a limited number of graduates and students and will comprise the study of pathology of the central nervous system and preparation as well as examination of microscopic preparations. This course is of especial value to prospective neurologists who wish to combine with their clinical knowledge a part of the pathologic manifestations of nervous diseases.

Berks County Medical Society, at its banquet, January 8, following the annual meeting, had as its guests Dr. Martin, professor of surgery at the University of Pennsylvania; Dr. Forbes, professor of anatomy at Jefferson Medical College, and Dr. John Shoemaker, professor of therapeutics at the Medico-Chirurgical College. The Society elected Dr. S. S. Hill president; Dr. James W. Keiser, recording secretary; S. Banks Taylor, corresponding secretary, and Dr. A. S. Raudenbush, treasurer.

The Medical Society of the County of Erie held its eightieth annual meeting January 8th, electing officers and delegates to the State Society. The following program was presented: **A county health officer**, by Dr. E. H. BALLOU, president; **A review of legislation in reference to tuberculosis**, by Dr. J. H. PRYOR; **A brief resume of the grosser animal nature, and its application in medicine**, by Dr. GEO. N. JACK; **Gastro-intestinal disease in children**, by Dr. W. C. CALLANAN.

Errata.—In the PHILADELPHIA MEDICAL JOURNAL of January 5, page 24, the prescription credited to Dr. Walter L. Pyle, should read: Yellow oxide, 1 grain; vaseline, 3 drams, instead of yellow oxide, 1 grain; vaseline, 3 grains. In the PHILADELPHIA MEDICAL JOURNAL of December 29, 1900, page 1237, in the article entitled "Rotary Lateral Curvature of the Spine; Their Diagnosis and Treatment," Dr. Daniel W. Marston should have been mentioned as the associate in the article of A. M. Phelps, A.M., M.D., instead of A. W. Marston, M.D.

Vital Statistics of Philadelphia for the week ended January 5, 1901:

Total mortality	453	
	CASES.	DEATHS.
Inflammation of appendix 4, brain 13, bronchi 8, kidneys 16, liver 1, lungs 60, peritoneum 4, pleura 1, stomach and bowels 17, tonsils 1		125
Inanition 13, marasmus 10, debility 3		26
Tuberculosis of lungs		61
Apoplexy 16, paralysis 6		22
Heart—disease of 31, fatty degeneration of 5, neuralgia of 2		38
Uremia 15, diabetes 2, Bright's disease 8 . . .		25
Carcinoma of breast 3, face 1, liver 6, stomach 1, throat 1, uterus 1, jaw 1, tongue 1		15
Convulsions		8
Diphtheria	118	20
Brain—softening of 2, congestion of 1		3
Typhoid fever	95	16
Old age		14
Burns and scalds		6
Teething		2
Dysentery		2
Suicide		3
Cirrhosis of liver		6
Alcoholism		4
Cyanosis		2
Gangrene of foot		2
Scarlet fever	92	3
Liver, abscess of		1
Abscess of stomach 1, asthma 4, atheroma 1, casualties 7, cerebrospinal meningitis 1, congestion of lungs 1, puerperal convulsions 1, croup, membranous 2, dropsy 1, erysipelas 1, fistula 1, hematemeses 1, hernia 3, influenza 7, jaundice 1, leukemia 1, locomotor ataxia 1, intestinal obstruction 1, pyemia 1, rheumatism 1, arterial sclerosis 1, septice-mia 1, sarcoma of liver 1, sarcoma of neck 1, suffocation 1, tumor of chest 1, ulceration of stomach 1, whooping cough 3, umbilical hemorrhage 1, dropsy 1		50

Pediatric Society.—At the meeting of January 3, Dr. S. M. HAMILL exhibited an infant, 6 months of age, which is suffering from severe anemia with leukocytosis. The child has been breast-fed since birth. The liver is slightly and the spleen considerably enlarged. Emaciation is moderate. Examinations of the blood show about 3,000,000 erythrocytes, leukocytes varying from 29,000 to 23,000, hemoglobin 42%. There is a great increase in the lymphocytes, nucleated reds are present, and there is marked poikilocytosis. There are no symptoms of rickets or scurvy and no syphilitic or tuberculous family history. There being no underlying disease on which to base a diagnosis of secondary anemia, the case was presented as belonging to one of the unclassified varieties between leukemia and pernicious anemia.

DRS. J. A. SCOTT and H. M. FISHER reported a case of **leukemia** in an infant 17 months of age. Leukocytosis has been as high as 105,000, and nucleated red cells and myelocytes are present. The spleen is hard and extends below the umbilicus. Large doses of *nux vomica* have seemed to give good results.

DR. E. E. GRAHAM exhibited a specimen showing **malformation of the bowel**. The anus was a blind pouch 1 inch in length, the lower end of the large bowel being 1 1/2 inches above this. An opening in the bowel was made when the infant was 4 1/2 days old, but death followed in 48 hours.

DR. E. J. MILLER showed a case of **nodding spasm**. The nodding has lately diminished, and nystagmus is present. There are evidences of rickets in the case, and Dr. Miller believes that disease to be the cause in the larger number of cases.

DR. WILLIAM PEPPER showed specimens from a case of **sarcoma of the liver** and right suprarenal capsule. The child lived 6 1/2 weeks, the increase in size of the abdomen being very marked. The liver was found to be enormously enlarged, weighing 2 pounds 8 ounces. The growth proved to be a typical lymphosarcoma, the suprarenal capsule being much more hemorrhagic than the liver. Dr. Pepper finds 5 other cases recorded, the time of beginning, the symptoms, appearance, and duration of life being strikingly alike in all of them. The cases differ from ordinary sarcoma of the suprarenal capsule, one point being that no pigmentation of the skin was present. The case is believed to have been one of congenital malignant disease.

Philadelphia County Medical Society.—The subject discussed at the meeting of January 9 was **typhoid fever**. DR. A. O. J. KELLY read for DR. J. H. MUSSER and himself the report of a case of **hemoglobinuria complicating typhoid fever**. The patient was a colored laborer, 21 years old, who had undoubted typhoid. During the first 6 days after his admission to the hospital, hemoglobinuria was present. This condition being present on admission excluded ice as a causative agent, and its use did not seem to increase the hemoglobinuria. The blood showed only 15% of hemoglobin for some days. There was no history of malarial fever in the case and recovery followed the attack.

DR. WILLIAM OSLER, of Johns Hopkins University, who was present by invitation, read a paper upon **Perforation and perforative peritonitis in typhoid fever**. Dr. Osler stated that physicians could not congratulate themselves on lessening the incidence of typhoid fever in this country, but that they could on the reduction of the mortality which should not now be above 7.5% for hospitals. This reduction in mortality is due to better nursing and treatment, there being a special class of formerly fatal cases which are greatly influenced by modern nonmedicinal treatment, namely, those suffering from toxemia. But of every 100 deaths from typhoid fever only 50 are due to asthenia, while 30 are the result of perforation and 20 are caused by other complications. There has been no material reduction in the mortality of perforative cases. Perforation is more apt to follow ulceration high in the bowel, but this situation is better for the surgeon. The most difficult cases are those where perforation is low in the bowel and occurs early in the course of the attack. Two clinical features are to be emphasized, first, the uncertainty and variability of perforation and, second, the necessity for a complete revision of the methods of recording cases by the medical man. The points to be considered are the perforation itself and the consecutive peritonitis. It is important to recognize the condition and operate within 12 hours after perforation. Three cases were detailed, each illustrating a certain class. The first class had the following symptoms suggesting perforation: Sudden onset of pain, persistence of pain, tenderness on pressure, muscular rigidity, increasing distention of the abdomen, movable dullness in the flanks. Against these, however, were: No fall in temperature, no increase in pulse-rate, no leukocytosis, no collapse. Operation was performed 9 hours after the symptoms began, and a perforation was found and sutured. The patient died in a day or two afterward. The wound in the bowel had almost healed. This patient is believed to have died of typhoid fever and not of peritonitis. The second case was one having hemorrhages. Operation revealed such a necrosed condition of the gut that sutures would not hold. The patient died on the table. In this case the symptoms

were attributed to hemorrhage when they should have been attributed to perforation. A point which should have been more noticed was that the liver-dullness was obliterated, though there was abdominal distention at that time. This belonged to a class of cases in which fatality is inevitable no matter when operation is done. The third case was a child operated upon 8 1/2 hours after perforation, an uneventful recovery following. The conclusion reached after a study of cases of which the above are types, is that sweating, hippocratic facies, feeble running pulse, collapse, etc., are not symptoms of perforation, but of peritonitis. What is needed is a fuller knowledge of the early symptoms of perforation. Dr. Osler does not believe that much is to be hoped for as regards the recognition of the so-called perforative stage; but it is the duty of the physician to study most carefully the earliest symptoms in perforation. In studying hospital notes, it is apparent that many points which should have been noted are left out. It is essential that every serious case of typhoid fever should be watched by a careful physician who is in constant touch with a surgical colleague. It is better that these patients be visited by a skilled resident-physician rather than by an interne. To leave them to the care of attending physicians is to lose cases. To direct attention to certain definite points, and aid in the early recognition of perforation, Dr. Osler gives the following specific statements to hospital physicians: 1. When a patient has abdominal pain, the night-superintendent or nurse is instructed to at once notify the physician of the onset of pain, hiccough, vomiting, rise of pulse, increase of respiration, collapse, or sweating. 2. The character of the pain (A) as to its onset—whether it is an aggravation of previous pain or whether it is sudden. Also whether it yields to ordinary treatment or recurs in paroxysms. (B) As to its locality—whether diffuse or local, in the iliac fossa or in the hypogastric region, if it radiates to head of penis, etc. 3. The state of the abdomen. (a) Inspection, whether flat, scaphoid or distended. If the latter, is it uniform or in the hypogastric or other region alone, note respiratory movements; (b) Palpation—note degree of tenderness, muscle rigidity or spasm; (c) Percussion—note the condition of the flanks and extent of liver-dullness; the latter should be marked out every 3 hours, remembering that obliteration may occur in a flat as well as in a distended abdomen; (d) Auscultation—the amount of peristalsis present and the occurrence of a friction sound; (e) Examination of the rectum and stools. 4. The general condition of the patient: (a) Change in expression—pallor, etc.; (b) pulse; (c) temperature; (d) respirations; (e) sweating—onset, etc.; (f) vomiting, relation to onset of pain; (g) hiccough. 5. Blood examination: leukocytosis, whether stationary or rising. The leukopenia of typhoid fever must be remembered in this connection. These statements should be of help to hospital physicians. It is in the hands of the profession to reduce the mortality of typhoid fever. One important preliminary to this result is practical, firsthand instruction in typhoid fever to senior medical students. This does not mean lectures or recitations but the actual seeing of cases and watching their progress throughout the attack. There are many lessons for physicians to learn, and one of the most important is that it is necessary to watch in severe cases for symptoms of perforation and to operate early. In this way it is probably possible to save one-half of the cases. One class of cases of perforation die whether operated upon or not, and a second class is saved from the peritonitis but dies of the fever itself, but it has been demonstrated by the surgeon that a third class exists which can be saved by operation. Eleven cases of perforation occurring in the wards of the Johns Hopkins Hospital have been operated upon with 5 recoveries. Out of 5 additional cases brought in and operated upon at once there was one recovery. In the discussion of the paper, DR. ERNEST LA PLACE stated that there must be a closer association of the physician and surgeon. The surgeon should from the first have a part in the treatment of typhoid fever as he does in appendicitis. Typhoid fever must in the future be more and more a hospital-treated disease, where nurses, physicians, and surgeons can watch the cases and where operation for perforation can be done promptly and under proper conditions. DR. JOSEPH PRICE agreed that young clinicians should receive more practical education in typhoid fever. Hospital training before a diploma was granted would be an ideal solution of the problem.

He would not hesitate to open the abdomen and ligate the bleeding vessel in a case of severe hemorrhage. Out of 22 operations for suspected perforation only 2 failed to relieve that condition. Ten of these patients are now well. The surgery practised by many surgeons is too much, the least possible being the best. Resection of the bowel is not recommended. When it will not hold sutures it is better to simply make the toilet of the abdomen and place a cofferdam of gauze. In 4 to 6 weeks afterward the resulting fistula can be repaired. In many cases of contaminated peritoneum and feeble pulse the patient leaves the table in better condition than before operation if that procedure be confined to the toilet and open treatment. DR. M. H. FUSSELL places the most confidence in obliteration of the liver-dulness as a symptom, yet this occurred in 1 case without perforation. In 1 case of perforation and death a marked peritoneal friction-sound had been present. DR. W. L. RODMAN believes that recovery after perforation is more common than is generally thought. Late reports of military surgeons regarding conservative treatment of gunshot wounds of the abdomen and intestines should have some bearing on the perforation of typhoid fever. Until the medical man tells more accurately how to diagnose perforation the surgeon must be rather pessimistic as regards operative results. In closing the discussion DR. OSLER stated his belief that recoveries following perforation are very rare. He does not remember a case recovering where the diagnosis was clear and peritonitis was present. A third year student can diagnose peritonitis 36 to 48 hours after perforation, but early diagnosis is needed. The clinician must go over the ground again and again and must be able to advise operation before general peritonitis is present. What if a few mistakes in diagnosis be made and no perforation be found? These patients bear operation well and should be given the benefit of the doubt. The clinician and general practitioner should be awake to the possibility of saving 30% to 50% of the cases of perforation. The practitioner can seldom say of any case that it would not have recovered without his aid, but the surgeon in many of these cases can say "I saved that life."

NEW YORK.

The New York State Medical Association has just issued the first publication of its monthly Journal.

Dr. Knapp's Gift.—Dr. Herman Knapp presented to the New York Ophthalmic and Aural Institute as a gift the buildings now occupied by that institution.

The State Board of Health in its monthly bulletin discusses the outbreaks of smallpox in 17 places in New York State, and believes that a troupe of traveling minstrels was responsible for the ingress of the disease.

New Children's Ward.—A committee was appointed by the Board of Health, at its meeting on December 27, to call on John N. Keller for the purpose of requesting that a new children's ward be established on Randall's Island.

Tuberculous Hospital.—The Legislature will be asked to appropriate \$100,000 for the erection of the first pavilion of the Tuberculous Hospital, which is to be located at Raybrook, about 4 miles east of Saranac Lake.

Prize.—Dr. M. Hartwig, President of the Buffalo Academy of Medicine, has offered a prize of \$50.00 for the best paper contributed by any member of the academy during his term of office. Papers must be handed in by July 1.

Dr. Lucius J. W. Lee died at his home in Brooklyn, on January 6, of pneumonia, aged 65 years. Dr. Lee was a great-nephew of the late Dr. S. D. Gross, of Jefferson Medical College, Philadelphia. He was a prominent practitioner in New York and Brooklyn for 27 years, having devoted the latter part of his years to the study of diseases of the stomach.

The New York City Board of Health.—The New York City Board of Health intends to establish regulations among barbers which will require the employment of clean tools and a fresh towel for each customer and the abolition of sponges and powder puffs. The frequent cases of barbers' itch that have resulted, due to the infection from unclean barbers' utensils, have made it necessary to establish these restrictions.

A Large Fire at the Rochester Orphan Asylum.—Twenty-eight bodies lie at the morgue and 12 others more or less seriously injured lie at the different hospitals in the city as a result of the terrible holocaust which occurred January 8 at the Rochester Orphan Asylum. Of the dead 26 were children, and 2 were adults. The fire was doubtless caused by an explosion of natural gas in the boiler room. It spread so rapidly that many of the 109 inmates were overcome by the flames and smoke, almost without warning.

Dr. G. T. Stewart Appointed Head of Bellevue.—The *New York Herald* of January 8 prints the following: Ordered—That Dr. George T. Stewart be and he hereby is transferred from the Metropolitan Hospital to Bellevue Hospital, with sole power to superintend Bellevue, Fordham, Gouverneur, and Harlem hospitals, and with power to suspend any interne, nurse, or other employe of the Department of Public Charities assigned to duty in Bellevue, Fordham, Harlem, or Gouverneur hospitals, whenever in his judgment the interests of the service shall demand such suspension.

Transactions of the New York Obstetrical Society.—Regular meeting held December 11, 1900, DR. J. H. BOLDT, president, in the chair. DR. E. P. CRAGIN presented specimens from two cases of **tumor complicating the puerperium** and requiring removal. Case 1, an ovarian cyst, the pedicle of which became twisted during the puerperium and requiring removal, occurred in a primipara. After delivery an ovarian cyst was found high up on the right side of the abdomen. On the fourteenth day of the puerperium fever set in and continued with fluctuations for some time; vomiting set in on the thirtieth day. An uneventful recovery followed the removal of the cyst on the right side, together with the left ovary, which was also the seat of a dermoid cyst.

Case 2 was that of a woman of 44, delivered at full term after a prolonged labor by means of low forceps application. The placenta had to be extracted manually. The woman, who had lost 38 ounces of blood, was in a very poor condition. Before the delivery a large hard tumor the size of a fetal head was found on the right side of the fundus of the pregnant uterus, and this tumor was removed on the thirty-second day of the puerperium by an abdominal hysterectomy. The uterus with the tumor weighed 8 pounds and 2 ounces. Discussed by A. PALMER DUDLEY.

DR. BRETTAUER showed a **specimen of ruptured tubal pregnancy** which had been removed from a woman of 29, married 6 years. The entire ovum was found free in the abdominal cavity. The patient died on the fourth day owing to a septic infection which emanated from necrosis of the abdominal fascia. Discussed by DR. BROTHERS.

DR. EDGAR showed a **metal pelvis and a metal fetal head attached**, as a contrivance to be used in the teaching of obstetrics; also several bottles and jars to be carried in a canvas case by the obstetrician. Discussed by DR. DICKINSON.

The paper of the evening was read by DR. MALCOLM MACLEAN entitled, **A plea for the recognition of some of the factors in the mechanism of labor.** He believed that in many cases injuries have resulted from ignorance of the principles governing the mechanism of labor, in which case the patient, child and physician were affected. He avoids too hasty interference when the mother's tissues are unprepared and rigid. The membranes should be left intact until the dilation is complete. When the latter has occurred and the membranes are stretched flatly across the mouth of the uterus with every pain, instead of protruding to the point of rupture, unnecessary delay may be avoided with propriety, by rupturing the sac. The importance of employing the fetal envelope as a rubber glove in intrauterine manipulation is emphasized, for if in this manner germs are introduced by the operator they will not reach the fetus but will subsequently come away with the membranes. According to the writer, douching after labor is not indicated since the sinuses are filled with sterile clots and these should not be disturbed in the endeavor to remove germs that may not exist. He advises chloroform when there is a too violent advance of the presenting parts through an unprepared vulva, but the anesthetic should only be given to the degree of obstetric anesthesia excepting in delivery by means of instruments. Discussed by DRs DICKINSON, EDGAR, SIMON MARX, and closed by DR. MACLEAN.

NEW ENGLAND.

Mercy Hospital.—At the annual meeting of the Mercy Hospital Corporation, of Springfield, Mass., held at the Hospital on January 2, the only change in the staff was the election of Dr. J. P. Black to the staff of assistant surgeons.

Thurber Medical Association.—At a meeting of the Thurber Medical Association, of Milford, Mass., on January 3, Dr. E. H. Trowbridge of Worcester, read a paper on "The Medicolegal Aspect of Fractures," reciting a large number of cases and presenting a collection of skiagraphs.

CHICAGO AND WESTERN STATES.

Dr. W. W. Cole, of Columbia, Ohio, has been appointed Director of Public Safety of that city.

New Hospital.—A charity hospital will be built at Eureka Springs, at a cost of \$5,000, by Mrs. R. C. Kerens, of St. Louis.

Resignation of Dr. Regensburger.—Dr. A. T. Regensburger has resigned the professorship of dermatology of the College of Physicians and Surgeons in San Francisco.

Missouri State Board of Health.—The following were elected at a meeting held at Jefferson City, January 4: Dr. C. K. Elkins, president; Dr. J. T. McClenachan, vice-president; Dr. E. C. McElwee, secretary.

Fire in Children's Free Hospital.—On the evening of January 3 fire broke out in the Children's Free Hospital of Chicago, resulting from the ignition of a Christmas tree. Several nurses, who, by their coolness, succeeded in removing all from danger, were slightly burnt during their efforts.

Smallpox in Kansas.—The schools of Columbus, Kan., as well as the District Courts have adjourned upon order of the State Board of Health, on account of the epidemic. There are 200 cases in Cherokee County. Almost the whole of the southeastern portion of Kansas is affected with this epidemic.

The College of Physicians and Surgeons, of Chicago, has received an endowment of \$25,000 from the dean of the school, Dr. W. E. Quine, for the purpose of the college library, and an endowment of \$25,000 from Dr. D. K. A. Steele, to be devoted toward the endowment of the pathologic laboratory.

Dr. William H. Sloan died on January 1, aged 54, having been an active member in Moline for 20 years, where he stood at the head of the profession. He was a member of various medical associations, and also took quite an interest in educational matters. He was a member of the Board of Education for 12 years.

Inherited Tendency to Tuberculosis.—The Indiana State Board of Health in its monthly bulletin cites the following: A farmer of Adams County died January 1, 1900, of pulmonary tuberculosis at the age of 80 years. His son died of the same disease on May 15, 1900, and the daughter of the latter died December 11, 1899, the cause of death also being pulmonary tuberculosis. It is remarked that it is possible that the elder farmer may have infected the home himself.

SOUTHERN STATES.

Dr. Foster Resigns.—Dr. George W. Foster has resigned his position at the Elizabeth Hospital for the Insane at Washington to accept an appointment as Superintendent for the Second Hospital for the Insane at Bangor, Maine.

Columbian University.—There was a meeting of the hospital board on January 3. The following officers were elected for the ensuing year: Dr. F. A. King, president; Rev. Dr. S. H. Greene, vice-president; Mr. S. W. Woodward, treasurer, and Dr. E. A. de Schweinitz, secretary.

Memphis Medical Society.—At the annual meeting for the election of officers held Friday evening, December 28, Dr. Frank A. Jones was elected president; Dr. Alfred Moore, vice-president; Dr. J. L. Andrews, secretary; Dr. Richmond

McKinney, reporter. The annual banquet was given at the Nineteenth Century Club.

St. Louis Academy of Medical and Surgical Sciences.—At the last meeting the following officers were elected for 1901: President, Dr. Emory Lanphear; senior vice-president, Dr. Carl Pesold; junior vice-president, Dr. H. S. P. Lare; secretary, Dr. O. L. Suggett; treasurer, Dr. G. M. Phillips; orator, Dr. William Porter, and librarian, Dr. H. G. Nicks.

Richmond Board of Health.—Dr. Greer Baughman, who for the past 2 years has been studying medicine in Vienna, has returned home. Recently he was elected demonstrator in physiology in the Medical College of Virginia.

Out of 24 cases of typhoid-fever reported for December, 4 were fatal; there were 5 cases of diphtheria with 1 death.

Senses Hospital.—At a meeting held on January 2, 1901, the Board of Trustees of the Senses Hospital of New Orleans, approved the appointment of Dr. Gordon King as surgeon in charge of the throat, ear, and nose department. An entertainment for the benefit of the hospital to be held at the French Opera House on January 18 is under preparation. Dr. E. Denegre Martin was appointed consulting physician of the hospital.

A New Drug Concern.—Arrangements have just been completed for the establishment of a new drug house in New Orleans. The senior member of the company is S. P. Nickels, who has been manager and local representative of the Parke, Davis & Company for the last 5 years. It will be the only concern of its kind south of Baltimore, and will devote its attention to the output of fluid extracts, tinctures, elixirs, etc., with a full plant for testing the physiologic action of various drugs.

MISCELLANY.

The rumor of President Elliot being about to resign has been officially denied.

Obituary.—HARVEY H. BURKAM, aged 61, at Foxville, Frederick County, Md.

Smallpox in Soldiers' Home has broken out in Leavenworth, Kansas, jeopardizing 3,000 veterans located there.

The Röntgen-rays succeeded in locating a \$5 gold piece which had been swallowed by a boy of Wabash, Ind., five years ago.

State Examination.—Out of the 19 physicians who took the recent Connecticut State examination, 14 were successful.

A new medical journal has been issued at Havana known as the *Revista de la Asociacion Medico Farmac. de la Isla de Cuba*.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended January 4, 1901:

SMALLPOX—UNITED STATES.			CASES.	DEATHS.

Dr. Eduardo Wilde, the Argentine Minister, one of the most distinguished representatives from South America, now in Washington, is also a physician. He has been chosen a delegate to the Pan-American Congress which will begin its session in Havana, Cuba, February 4, 1901. Dr. Wilde intends to present a new plan for establishing sanitary regulations in the ports of the whole of America.

Changes in the U. S. Marine-Hospital Service, for the week ended January 3, 1901:

PURVIANCE, GEORGE, surgeon, relieved from duty at Baltimore, Md., and directed to proceed to Washington, D. C., reporting at the bureau for duty. December 29.

WERTENBAKER, C. F., passed assistant surgeon, to proceed to Shreveport, La., for special temporary duty. December 28.

STIMPSON, W. G., passed assistant surgeon, to proceed to Denver, Col., for special temporary duty. January 1.

BROWN, B. W., passed assistant surgeon, relieved from duty at Cape Charles Quarantine, and directed to proceed to Baltimore, Md., and assume command of the service, relieving Surgeon George Purviance. December 29.

WILLE, C. W., assistant surgeon, to assume temporary command of Cape Charles Quarantine, relieving Passed Assistant Surgeon B. W. Brown. December 29.

AMESSE, J. W., assistant surgeon, on being relieved by Assistant Surgeon L. H. P. BAHRENBURG, directed to proceed to Manila, P. I., and report to chief quarantine officer for duty. January 2.

LLOYD, B. J., assistant surgeon, granted leave of absence for 18 days from December 11. January 3.

BAHRENBURG, L. P. H., assistant surgeon, bureau order of December 27, 1900, directing him to proceed to Manila, is revoked, and he is directed to proceed to Honolulu, H. I., reporting to the chief quarantine officer for duty. December 31.

BREADY, J. E., acting assistant surgeon, granted leave of absence for 4 days from January 2. December 28.

KOLB, W. W., hospital steward, granted leave of absence for 30 days from January 29. January 2.

OLSEN, E. T., hospital steward, granted leave of absence for 5 days. January 2.

CASUALTY.

BOOTH, A. R., acting assistant surgeon, died at Shreveport, La., December 27, 1900.

Changes in the Medical Corps of the U. S. Navy, for the week ended January 5, 1901.

CRANDALL, R. P., surgeon, detached from the U. S. T. S. "Constellation," upon reporting of relief, and ordered to recruiting duty at Milwaukee, Wis., and then home to wait orders.

McCLURG, W. A., surgeon, detached from the "Indiana," and ordered to the Naval Training Station, Newport, R. I.

BRISTER, M., J. assistant surgeon, ordered to the "Independence," January 13.

The unveiling of the busts of **Graefe** and **Schweiger** took place on the 16th of December, 1900, in the amphitheater of the University Eye Clinic.

Foreign News and Notes.

GREAT BRITAIN.

Dr. Arthur Robinson has been elected lecturer on anatomy at King's College.

New Zealand Medical Journal.—A medical journal has been established at Wellington, edited by J. Malcolm Mason, and issued by the New Zealand branch of the British Medical Association.

CONTINENTAL EUROPE.

Professor Wollenburg has succeeded Professor Siemerling in Tübingen.

Influenza in St. Petersburg.—Influenza has appeared in epidemic form in St. Petersburg.

The Saxon Ministry.—The ministry at Saxony now requires that physicians, hospital managers, and keepers of boarding-houses report all cases of tuberculosis.

At a meeting of the Société de Chirurgie of Paris, M. Chaput related a case in which a woman had a tampon removed from the abdomen that had been there for seven years.

Artificial Spectrum.—The Zeiss optical works in Jena are producing an artificial spectrum, which consists of four colored glass prisms. The colors employed can be combined so that almost any desired shade can be produced.

The oldest qualified physician in the world resides in Karlsbad, who is the son of Gallus Ritter von Hochburger, M.D., royal councillor of the Austrian Court. He is 97 years of age, has been in practice for 71 years, and he is in the full possession of his mental faculties.

Medical University at Beyruth.—The final examination by the faculty took place a short time ago in Turkey. Seventeen students obtained their diplomas. The course lasts four years, the annual tuition fee being 160 francs. The diploma confers the authority to practise medicine both in France and Turkey.

Tea and Alcohol in Russia.—The New York Sun, in a recent issue, states that tea was first imported into Russia in 1838. Nearly one pound per year is now consumed on an average by each inhabitant. The total consumption of tea in Russia is 106,000,000 pounds, and the total cost thereof about \$88,000,000. For brandy, beer, and wine, \$550,000,000 are expended. It seems that the use of tea is increasing rapidly relative to the alcoholic beverages. It is worthy of mention that this has taken place since the introduction of machine-made teas from Ceylon and India.

Death from Embolus, with Autopsy.—Robinson (*The Medical Age*, November 25, 1900) reports the case of a woman of 46, upon whom he did a vaginal hysterectomy for hypertrophic myometritis. The ovaries and tubes were surrounded with adhesions, which were broken up, but these organs were not removed. She did well for 17 days after the operation, when she complained of pain in the right leg and thigh. To test the sciatic, the author flexed the leg on the thigh and extended the leg, but no pain was elicited. In about 2 to 4 minutes thereafter the patient screamed with pain in the chest, the pulse rose to 140, the breathing to 47 and pallor supervened. She died in 45 minutes. At the necropsy an embolus was found at the bifurcation of the pulmonary artery. The left ovarian vein was filled with a fibrous coagulum about the thickness of a lead-pencil. The left kidney contained an elongated calculus, which accounted for pus in the urine. The gallbladder contained about 150 hepatic calculi, which had given rise to no symptoms. The author considers it remarkable that the left renal calculus should cause pain in the right leg and thigh. The pain suffered by the patient was continuous and severe. The lesson to be drawn from this is that patients operated upon should remain quiet for a sufficient length of time after the operation. [A. B. C.]

1.—Heath in a clinical lecture on **syphilitic diseases of the tongue** calls attention to the fact that induration of the sore in this location may not be present to the degree that it is on the genital organs. Sores upon the lips and tongue that are accompanied in the young by rapid lymphatic enlargement under the jaw are strongly suggestive of chancre. The communicability of syphilis by mucous membranes is not questioned today, and, therefore, a specific infection of the tongue or of the lip may innocently be produced, although it is possible that abominable practices are often responsible for direct inoculation into the tongue. **Drinking utensils and pipes** may also convey the virus. He presented a patient with a secondary eruption of syphilis and of mucous tubercles similar to the mucous plaques seen about the female genitals. As in the female genitals, the author considers that various mucous surfaces in the mouth which frequently are brought into apposition may mutually infect each other. Several illustrations were presented showing syphilitic ulcerations of the tongue. **Thickening of the tongue** is a frequent associated factor and may cause the patient considerable alarm, and for treatment of this condition he pushes mercury in the form of a mercurial mouth-wash of perchlorid of mercury, from 1:2000 upward, to be held in the mouth for 5 minutes by the watch. Mercury at the same time is also given internally, and most satisfactorily by inunction. The sulphur baths at Aix-la-Chapelle are not responsible for a cure, although very pleasant, but it is the daily inunction of mercury by the attendants which is fruitful of the beneficial results that have been so frequently obtained. Syphilitic affections of the tongue may occur, which appear to border between secondary and tertiary stages; these are in the nature of lacerations that are not actually gummatous in character. In discussing **tertiary syphilis** of the tongue, he mentions a case where throughout the substance of the tongue there were disseminated little nodules consisting of syphilitic deposit which did not yield to antisiphilitic treatment, malignancy being suspected. The whole tongue was excised, and upon microscopic examination a distinct epitheliomatous condition was found in addition to the gummata. The author believes that any continued irritation, such as a pipe, may give rise to epithelioma. **Leukoplakia** may occur entirely distinct from syphilis, tobacco being usually the cause. He believes that the addition of tobacco will greatly aggravate a subject already affected by syphilis. **Hyper-**

trophy of the papillae of the tongue should not be confounded with syphilitic warts that are frequently seen at the back of the organ. [M.R.D.]

2.—Southam reports 50 cases operated upon, of which 35 were males and 15 females. The **duration of symptoms** varied from several months to 6 years. The majority of cases occurred in persons between 20 and 30 years of age. In forty cases the patients had had 3 or more **recurrences**. Operation is advised when a second attack has made its appearance, notwithstanding that local symptoms may not be present during the interval of quiescence. **Suppuration** occurred in 15 cases and was usually found accompanied by a perforation of the appendix. **Fecal concretions** were found in 7 cases, but only in one instance was a true foreign body found in the shape of a pin. **Adhesions** were present in most of the cases, but their presence or absence were at variance with a number of attacks or their severity. In nearly every case there was thickening of the walls of the appendix and sometimes entirely occluding its lumen. [M.R.D.]

3.—Grossman considers **color testing** by means of **Holmgren's wools** as insufficient in many cases, as it is only a daylight test as used at present. The variability of the quality of light, and the disadvantage at times owing to **dark days** are both considered by the author to give rise to inconvenience. The solution is found by employing a set of colors adapted for a certain artificial light. **Central color scotoma** is a very serious objection, especially because it may be acquired or even transient, as in tobacco amblyopia. It sometimes occurs that the color-blindness is overlooked by the faulty examination (Holmgren) and only subsequently detected while the individual is performing his actual requirements. If a color signal be sufficiently close to the observer it may be strong and large enough to exceed the area occupied by the scotoma, and therefore the test-object must be, (a) variable in color, (b) variable in size, (c) variable in intensity. [M.R.D.]

4.—Barling states that the diseases of the **pancreas** are not well understood for two reasons: First, on account of the position of the organ, it cannot be easily examined, and, second, at autopsy the organ is not often examined. He reports 4 cases in which enlargement of the head of the pancreas was found when operating on the gallbladder or the ducts, 2 of the cases being errors in diagnosis as the symptoms were attributed to **gallstones** which were not found at the time of operation. The feature in these cases was enlargement of the head of the pancreas, producing a blocking of the common bile-duct and associated attacks of colic. It is further stated that on account of the relation of the head of the pancreas to the common bile-duct and the pancreatic duct, obstruction may be produced from swelling of the head of the pancreas probably as result of inflammation. It is also stated that colic is rarely encountered from pancreatic calculi owing to the **feeble muscular power** of the duct of Wirsung. Colic due to a pancreatic calculus is characterized by the position of the pain, which is either between the xiphoid cartilage and the umbilicus or in relation to the left costal arch. It is not unreasonable to infer that owing to the anatomic relation of the pancreatic duct and gland, that infection is liable to occur from invasion of the microorganisms of the intestines into the organ, causing an inflammatory swelling of the gland, such as often occurs in the salivary glands. The common bile-duct may in this way be compressed, giving rise to jaundice. [F.J.K.]

5.—Rolleston and Crofton-Atkins report a case of **congenital hypertrophy of the pylorus** producing **stenosis** in a full-term infant, which showed no external abnormalities. The early symptoms were vomiting and convulsions which developed when the infant was a fortnight old. Diarrhea developed a week afterwards. Subsequently the vomiting increased, the vomited material being highly acid. The child lost weight, and constipation became a serious and troublesome symptom. Death occurred when the infant was 7 weeks and 5 days old. At the autopsy, great hypertrophy of the pylorus was found with almost complete obliteration of the lumen. The wall of the pylorus measured 8 mm. The circular muscular coat measured 4 mm., the longitudinal coat 2 mm., and the mucous coats 2 mm. in thickness. Upon microscopic examination it was found that the mucous membrane of the pylorus was healthy, and the circular muscular coat showed some small-celled infiltration.

The mucous membrane of the stomach revealed catarrhal inflammation. The gastritis was believed to have been a late manifestation, as blood was found in the vomit 5 days before death. [F.J.K.]

6.—Reynolds states, in discussing the cause and symptoms of **epidemic arsenical peripheral neuritis** amongst beer-drinkers, that he has ascertained the source of the arsenic—the arsenic being found in the sulfur compounds from which sulfuric acid is made. The arsenic has also been found in the urine of patients after partaking of beer. In acute cases diarrhea occurred, and in the suckling infant diarrhea and vomiting developed. The nails were affected in a few cases. A few symptoms are reported which he has not yet seen described. In fair complexioned individuals the skin pigmentation is absent or is but slight and showing itself as a deeper pigmentation of preexisting freckles. The eruption is in many cases at first erythematous, then becomes darker, later marked pigmentation develops, and finally this is followed by desquamation that persists for several weeks. Bullae are rare. Herpes zoster occurs in a number of the cases and is not very uncommon. One case of partial anesthesia of the left fifth cranial nerve was observed, and a few cases of neuralgia of some of the spinal nerves without herpes. Marked cardiac asthenia, shortness of breath, exhaustion upon slight exertion, sometimes substernal and epigastric pain were noted and in many cases bronchitis and dilation of the heart were distinctive features. Even hemoptysis was noted in a few of the cases. Hoarseness was attributed to the swelling of the vocal cords and not to paralysis. He reports having seen 150 cases since November 13, 1900, and since that time 4 deaths which were due respectively to the following causes: Heart failure (one case); dilation of the heart with edema and bronchitis (one case); and gradual heart failure, exhaustion and extensive paralysis (two cases). He states that it is impossible at present to determine which symptoms should be attributed to the arsenic and how many to the alcohol. The differential diagnosis between beriberi is difficult and he believes that the skin lesions of arsenical neuritis are the distinguishing features. Severe heart failure and some mental confusion does not develop to the extent as is so common in alcoholic paralysis. As to treatment he endorses, with a few exceptions, the plan as directed by Dr. Judson Bury in the *British Medical Journal* for December 8, 1900. Sodium salicylate, antipyrin, and potassium iodid he believes should not be employed because of their depressing effects. Rest in bed, small doses of digitalis and liquor strychniae in tonic doses are recommended in the early stages. Bismuth and soda are used in cases that present symptoms referable to the stomach, and morphin is given in small doses for the relief of pain. [F.J.K.]

7.—Samways believes that, as the strength of the **hypertrophied bladder** is considered to possess no greater preventative power against rupture than the bladder in a normal condition, that there is, therefore, a greater risk for rupture in a bladder that is hypertrophied. It appears that the bladder usually hypertrophies in such a way that there is no increase in its resisting power. He compares the mucous membrane between the fasciculi to the netting covering a thin rubber ball as seen in spray apparatuses. As such netting guards against a too great expansion of the ball, so the fasciculi act in a similar manner. Mathematically the strength of a segment is increased inversely to the size of the sphere of which it is a part. A hypertrophied bladder therefore is strengthened throughout its whole wall. Should spontaneous rupture occur it is probably due to additional pathologic changes rather than errors of disproportion in mechanical resistance. [M.R.D.]

8.—Blumer reports a case of **intraperitoneal rupture of the bladder**, occurring in a laborer of 35, in consequence of a fall. The patient fell striking his abdomen on the curbstone, followed by inability to micturate. Upon examination there was considerable distention of the abdomen, tenderness on pressure and absolute dullness on percussion across the whole of the abdomen, and extending a little above the umbilicus. Upon catheterization, 196 ounces of bloody urine were evacuated. The diagnosis having been established, laparotomy was performed under chloroform-anesthesia. A vertical tear at the posterior wall of the bladder, extending into the peritoneum, was sutured. At the end of the tenth day, the whole length of the wound burst open and a large slough was taken out. Cystitis now set in, but

rapidly healed under boracic-acid irrigations, and salol internally. The case is unique on account of the little trouble caused by the large amount of fluid in the abdomen, and also, as the history shows, that the patient walked over 2 miles, 4 days after the injury. The absence of symptoms of peritonitis is also worthy of mention. [M.R.D.]

9.—Butler-Smythe records an interesting case of profuse **hydroperitoneum** in a woman 40 years of age, the fluid resulting from the presence of an immense fibromyomatous tumor. He believes that the hydroperitoneum resulted directly from an injury to the peritoneal covering of the tumor following an accident, the patient having been knocked down by a cart, thereby receiving contusions of the abdomen and lower extremities. Aspiration had to be performed 5 times in six weeks, and about 20 pints of fluid was evacuated at each time. Upon removal of the tumor through the usual supravaginal incision, it was found to be a simple multinodular fibromyoma without signs of malignant or other degeneracy. The peritoneal lining, however, was thick and injected; the tumor was not edematous. The symptoms disappeared rapidly after the removal of the growth. This case is of unusual interest because of the rarity of this complication in patients otherwise free from thoracic or abdominal disease. [W.A.N.D.]

10.—The growth of fungus in the external auditory meatus is apparently a rare disease in temperate climates, but according to the author's 8 years of experience it is very common in the tropics. The symptoms vary from simply a sensation of **occlusion of the ear** to a considerable amount of watery discharge. The disease is usually bilateral. The physical signs in typical cases are, occlusion of meatus by a soft wool-like substance of a pale lemon yellow or yellowish-green color. There may be some desquamation of epithelium at the walls of the canal. In chronic cases, in addition to soft masses of recent fungus there may also be inspissations resembling sodden newspaper. Microscopic examination reveals *penicillium glaucum*, *aspergillus*, and, more commonly, the *mucor mucedo*. Complications are diffuse inflammation of external auditory meatus, acute serous and chronic catarrh of the middle ear, perforation of the membrana tympani, swelling and even abscess of lymphatic glands at angle of jaw, and eczema of the meatus and pinna. Diagnosis—settled by microscope. Prognosis—favorable, if treated by physician himself. Treatment—remove as much of fungus as possible, syringe with warm solution of bichlorid of mercury 1:5000, dry, and sponge with solution of bichlorid of mercury and alcohol 1:1000. Plug with sterile cotton-wool. After fungus ceases to grow, insufflate a powder of boric acid, 2 parts; bismuth salicylate, 1 part; oxid of zinc, 3 parts. Prophylaxis consists in preventing entrance of sea water to the ear. [M.R.D.]

11.—Tubby emphasizes the following points, in the treatment of **spinal abscesses**: 1. Do not wait to open a spinal abscess until the skin is reddened and involved. 2. So far as possible open the abscess at certain "seats of election," the places of evacuation to be decided by the direction taken by the abscess and by the surgeon. 3. Wherever evacuation is decided upon, let it be done as far as possible away from the groin, and in such a position that more than one opening can be made into the abscess cavity. 4. Carefully cleanse the cavity and rub the interior thoroughly with menthol or iodoform solution. 5. Avoid drains of all kinds. 6. Be careful to carry out perfect aseptic measures from first to last. When patients are placed at rest with the hopes of causing absorption of fluid, the abscess often makes its way to the surface. For irrigation he employs a modification of Jones' solution, viz: Menthol 1 grain, rectified spirits 1 ounce, parolein $\frac{1}{2}$ pint. He sutures the wounds, avoiding drains, because of secondary infection with pyogenic bacteria, and because a drainage tube frequently converts a healthy incision into a tuberculous sinus. [M.R.D.]

12.—For restoration of the lower lip following excisions of epitheliomata, Kennedy considers the flaps taken from the side with bases below to be the best. The author's case was a man of 78, who had a warty and partially ulcerated growth of lower lip that had recurred after 16 years. An illustration of the patient is presented, showing the restoration after excision of entire lower lip. In former operations there was a scarcity of mucous membrane and difficulty in occluding the gaps which remained after raising the flaps to the level of the lip. [M.R.D.]

13.—Miller reports 2 cases of blindness due to sphe-

noidal and ethmoidal sinus disease. The clinical course of the author's first case consisted of cœna, necrosis of the nasal septum, sphenoidal and ethmoidal sinus disease, cerebral complication and death. The turbinates were considerably atrophied and there was considerable discharge of fetid pus from the ethmoidal cells. The perpendicular plate of the ethmoid was considerably affected by the necrosis. After unconsciousness and convulsions, the patient became blind within 48 hours; pupils reacted slightly to light, of which, however, there was no perception. Paleness of both discs was now observed. In the second case reported, illness began with a small **sore in the roof of the mouth**, followed by failing vision about 2 months later, with entire blindness within 4 or 5 days. There was a history of a **nasal discharge** 3 months before admission. In this case there was a very large perforation of the nasal septum, and granulation tissue invaded the ethmoidal region. The sphenoidal sinus was punctured 1 month after admission. Beginning atrophy of the optic nerves was then noticed. The necropsy showed that the ethmoid was soft and considerable pus present in the ethmoidal cells. Throughout the whole brain there was a general softening, but without fluid in the ventricles. The author surmises that in these cases there was not a true cœna on account of the extensive loss of bone tissue. He believes that cases of this nature should be considered as **syphilitic ones**, and that surgical intervention is the only means of relief or cure. [M.R.D.]

14.—Kirk reports an operation for complete prolapse of the rectum by intraabdominal fixation, the patient being a male child of 1 year of age. He prefers this method to the operation commonly performed in these severe cases—namely complete removal of the prolapsed portion of bowel—on account of the success attending the similar operation of ventral fixation of the uterus, and on account of a dislike to mutilate the lower part of the rectum for fear of giving rise to stricture or incontinence. The only objection to this apparently ideal operation is the risk of a subsequent ventral hernia, and this can be minimized to a great extent by splitting the muscles and aponeuroses as far as possible, and not cutting them. The child made a rapid recovery and the laparotomy scar has remained quite firm. [W.A.N.D.]

2. On Some Disappointments of Surgery. D'ARCY POWER.
3. Observations on Compressed-Air Illness. FREDERICK R. WAINWRIGHT.
4. Interesting Surgical Cases. E. PAGET THURSTAN.

1.—Latham believes that one of the most important factors in tuberculous infection in childhood is a contaminated milk-supply, the bacilli entering from the intestinal tract. This appears to be first infected by the fact that the first signs of tuberculosis usually occur in the lymphatic glands, and infection usually takes place in childhood, during the period of milk-feeding, that is to say, the disease is quite common from the age of 6 months to 2 years, and then rapidly diminishes in frequency. It is interesting to note that with the improvements in the hygienic conditions, particularly in regard to the milk-supply, that has taken place in the last 20 years, there has been a gradual diminution in the number of cases of tuberculosis occurring in childhood. Apparently during this age the general method of distribution throughout the body is through the lymphatic system, and it is not, as commonly supposed, in the direction of the lymphatic stream, but against it. Not infrequently the infection occurs in the tonsils. In 45 tonsils removed from children varying from 3 months to 13 years, 7 produced tuberculosis in guinea-pigs into which they were inoculated. Among the varieties are: Tuberculosis of the bronchial glands, miliary tuberculosis, and tuberculous bronchopneumonia. The first rarely causes symptoms. There is sometimes harsh breathing, with prolonged expiration; dulness may be made out in the back from the spines of the second to the fifth dorsal vertebra, and occasionally the compression may be so severe as to interfere

with entrance of air into one of the lungs, or partial occlusion of a vein may give rise to a venous hum, or edema of the face or arms. Miliary tuberculosis is characterized by wasting, moderate temperature, and towards the end, hurried respiration, cyanosis, and rales in the lungs. Tuberculous bronchopneumonia gives rise to physical signs similar to those of simple bronchopneumonia, although the fever is ordinarily not so high. It usually commences more insidiously, there are periods of remission, and often a crop of downy hair on the back of the child, although the relation of this in the disease is not understood. Not quite as frequently we have pulmonary tuberculosis similar to the form that occurs in adults. The treatment consists of the avoidance of further infection, fresh air, sunlight, abundant food, the avoidance of fatigue, and occasionally small quantities of stimulants. Among the drugs, cod-liver oil (if it is absorbed), creasote, and iodid of iron may be used. [J.S.]

2.—Power calls attention to various **disappointments** that occur after the simplest operations, and after such which generally lead to a permanent cure. Some of the disappointments in **circumcision** are removal of too much foreskin and retraction of the glands. In the operation for **hare-lip**, disappointments arise from the formation of a notch at the lower portion of the scar in the lip. **The recurrence of adenoids.** He mentions a case of **atresia of the anus** operated upon, in which it was found that the rectum opened into the vagina. **The renal calculi** imbedded in the substance of the kidney are sometimes impossible to detect, and even after exploratory incision into the kidney, disappointments are in store for the operator. The fixation of **movable kidneys** may give rise to disappointments to both patient and surgeon. Exhaustion may be so profound during internal strangulation of the bowel that operative procedure, although well performed, may fail to relieve. One should be guarded in making promises when operating upon the vermiform appendix, as the latter sometimes cannot be found, even after extensive dissection and careful exploration. **Mental disturbances** after surgical procedures give rise to many surgical disappointments. The author mentions the various disasters following **fractures**, formation of **conical stump** after amputation, especially in children. Some **dislocations** cannot be reduced, and others with great difficulty in spite of the apparently easy methods of reduction as described in textbooks. [M.R.D.]

3.—Wainwright in discussing the effects of compressed air upon the human body, calls attention to a possible etiological factor in the high temperature of the compressed air, having often observed a rise of from 60° F. to 115° F. during locking in. During the work on the Baker Street & Waterloo R. R. excellent ventilation was obtained by the escape of the compressed air, and by providing artificial ventilation when this was impossible. As an additional prophylactic the men were obliged to put on dry clothing after leaving the tunnel, were kept for some time in a well-warmed room, and given hot coffee. Altogether 47 cases of illness occurred in 120 men from May to October. The symptoms were, pains in the ears, in the nasal sinuses, and in carious teeth. In rare cases there was rupture of the tympanum. Upon leaving the lock the patients sometimes suffered from pains in the joints, most frequently the knee-joint, and occasionally from pains in the muscles. This pain was sometimes so severe that the patient became pallid, perspired freely, had a hard rapid pulse, and cried and groaned. It sometimes persisted for several days or even weeks. It did not always appear immediately after leaving the tunnel. Among the cerebral symptoms were headache, giddiness, and flashes of light before the eyes. In one case typical paraplegia occurred with involvement of the bladder and rectum. No cases of sudden death occurred. Among the interesting cases he records the following: The patient, a man of 50, somewhat stout, a half an hour after leaving the tunnel had severe pain in the front of the chest, there was then dyspnea, a sense of impending death, cyanosis, with rapid feeble pulse. Upon auscultation there was a harsh creaking and tearing sound heard throughout the whole respiratory course in the front of the chest. Percussion was negative, and in a short time the peculiar sounds disappeared, the man was re-compressed to 18 pounds and immediately relieved. Pressure was gradually decreased, and the patient left the lock perfectly well, and had no subsequent symptoms. The factors concerned in producing these symptoms are: Deficient

ventilation, too rapid locking out, too long a sojourn in the compressed air, and of course the condition of the patient; age, alcoholism, and obesity being serious predisposing factors. Regarding the way in which these symptoms are produced, Wainwright states that the exhaustion theory does not accord with the observed facts, neither is there any reason to suppose that there is excessive congestion of the central nervous system. There does seem to be reason to believe that the blood discharges the excess of gases it contains upon release of pressure, and that this may produce the various symptoms. This explains satisfactorily the immediate relief of the symptoms if the patient is replaced in the lock. In one case marked arterial sclerosis was observed in a man who had worked for 7 years at high pressures; otherwise no possible remote effects were observed. The treatment consists essentially of recompression; nothing else is really required. In conclusion Wainwright reports 8 additional cases, in one of whom there was apparently emphysema of the arm. [J.S.]

4.—Thurston describes 24 surgical cases occurring in the practice of Dr. E. J. A. Haynes, and the author, in Western Australia, each of which present features of special interest: 1. **Left ovarian cyst** in a woman of 21, in whom the peculiarity was a severe menorrhagia which in its severity rather indicated uterine than ovarian affection. Uninterrupted recovery after ovariectomy. 2. **Carcinoma of the liver** with no symptoms generally indicative of this affection. The diagnosis was made after the exploratory incision. Death a few months after. 3. **Extrauterine fetation**; laparotomy; death. 4. **Perinephritic abscess**; abdominal section. In this case, after the abdominal incision, a tense tumor containing considerable pus was found, making it doubtful whether it was a localized psoas abscess or a perinephritic one. As no harm was done to the spine, or any other symptoms present indicating a psoas abscess, it was presumed that it was a perinephritic one. 5. **Left extrauterine fetation**; laparotomy; death. 6. **Left extrauterine fetation**; anti-laparotomy; pelvic cellulitis; death. 7. This interesting case was one of **hydatids of the brain**. Upon trephining over the region of the fissure of Roland hydatid fluid and cysts were found. The convulsions and hemiplegia which had existed improved. Extensive involvement of the brain caused death within three months following the operation. An early diagnosis might have led to recovery. 8. This case of double pyosalpinx even after abdominal sections refused to subside until hydrogen peroxid and formalin were employed, when rapid improvement followed. A collection of pus in Douglas' sac was subsequently evacuated per vaginam. 9. Medical treatment having failed to benefit a **tuberculous kidney**, the left kidney was removed. Abscesses were found in the organ and the peritonitis which followed showed that **purulent infection of the kidney** must necessarily be followed by involvement of the perineum. 10. In a married woman a tumor with fluctuation was located, situated in the right epigastrium. Uninterrupted recovery followed an abdominal section for the growth, which proved to be a hydatid cyst. 11. In this case upon abdominal section, three **uterine fibroids** were found attached to the fundus, the posterior portion of which was adherent. The patient, a married woman, being in very low condition from previous hemorrhages, hysterectomy was not performed, but the patient made an uninterrupted recovery after the **removal of both ovaries**. 12. Appendicitis with suppuration; evacuation of pus without appendicectomy; recovery. 13. A woman who had been treated for appendicitis, upon abdominal incision was found to have a **patent Meckel's diverticulum** adherent to two coils of ileum, from which it was successfully, but with considerable difficulty, dissected; complete recovery. 14. A married woman from whom an ovarian tumor had been removed in the usual method, was seized on the third night after the operation with dyspnea and pain in the left chest. Death resulted probably from pulmonary embolism. 15. A married woman having been afflicted with constant **epileptiform paroxysms**, which had failed to subside under the administration of a great variety of drugs, was relieved by the removal of both ovaries. 17. After the removal of both ovaries from a married woman who was slowly bleeding to death from an enormous **uterine fibroid**, uninterrupted recovery set in, with shrinking of the tumor to half of its former size. 18. In this case a woman who was almost moribund from hemorrhage due to carcinoma of the cervix

uteri was still able to get about 12 months after the **removal of the blood-supply**, which was accomplished by tying the ovarian arteries on both sides with the round ligaments, as well as the arteries of the uterus. 20. A patient with pain in the abdomen, vomiting, and convulsions, who had a tumor an inch above M. Barney's point, was found upon abdominal section to have had an **internal strangulation** in the ileocecal fossa into which a loop of the ileum had passed. The bowel was withdrawn and uninterrupted recovery followed. 24. Recovery followed ligature of the vein and artery for **traumatic varicose aneurysm** of the thigh. [M.R.D.]

5. The Importance of Postoperative Treatment after Removing Spurs of the Nasal Septum. E. F. SNYDAGER.
6. Observations on Nitrogenous Metabolism in a Case of Nephritis. WALTER C. KLOTZ.

1.—With our present knowledge and the actual practice of the public in the matter of seeking medical advice, not more than 25% of patients are brought under **treatment for pulmonary consumption** until the disease is well advanced. It is quite clear, therefore, that in considering the **sanatorium treatment** of consumption we must have 2 distinct objects in view; (1) the cure of the disease, and (2) the prolongation of the lives of patients and the removal of infectious cases from surroundings in which they are a menace to the health of others. Bryce calls attention to the fact that if municipal sanatoria are established, provision must be made for patients who are in an advanced stage of the disease as well as for those who are in the primary stage. The erection of cottage hospitals, therefore, is a necessity. In such an institution one of the first rules that must be insisted upon, if the desired results are to be accomplished, is that patients shall not be allowed to discuss their own or other cases with persons other than the proper officials. Systematic means must be taken to provide wholesome mental employment for the patients. Consequently, the patient's time should be carefully divided and each one should keep a time card on which the daily routine, previously prescribed, is kept recorded as regularly as one should keep a diary. Actual treatment should begin with the arrival of the patient, when he should be put to bed and kept there if the afternoon temperature rises to above 100°. During his stay in bed the patient should be wheeled daily to an open window or protected balcony. Symptomatic treatment of the pyrexia is, as a rule, not necessary. When the fever has been reduced for several days, the patient is allowed to recline on an adjustable reclining chair on a protected balcony. This treatment in some sanatoria is continued from 9 A.M. to 9 P.M., after which the patient goes to his bedroom where, even in winter, the window is left open all night, a screen keeping off the wind. The condition of the patient must determine when gentle exercise may with advantage be added to the treatment. As an adjunct a more or less elaborate system of hydrotherapy may be adopted. A generous and nutritious diet of well-cooked and palatable food which is easily digested is productive of the best results. The utility of fats and oils depends upon three factors: 1. They serve, owing to their oily nature and to their being broken up in the intestine into fatty acids and glycerin, as laxatives and lubricants of the intestinal walls. 2. They are but slightly acted upon by bacteria, although in the absence of bile and pancreatic juice they may be decomposed into fatty acids and be largely discharged unabsorbed. 3. When absorbed by the columnar epithelium of the villi, they are carried directly to the central lacteals, and thence directly to the thoracic duct, instead of going, as in the case of starches and proteids, into the portal circulation for elaboration in the liver. Except in patients with strong di-

gestions, alcohol is contraindicated except as a temporary stimulant, owing to its disturbing effects upon the glycogenic function of the liver. If, however, ales and porter are well borne they will prove of value as productive of heat and energy in the reconstruction of tissue. Meat, milk, eggs, and similar articles of diet should be used up to the limit of their assimilation by the system. In patients who are deprived for a time of the privilege of active exercise the value of massage as an aid to the metabolic changes taking place in the tissues cannot be overestimated. Reduced air-pressures are a direct means of deepening the inspirations and of setting unused corners of the lung tissue to work; if scientifically practised, this method will probably develop a definite therapeutic value. The personal hygiene of the patients is a very important part of the routine. In very few instances can patients return to the sedentary pursuits of city life. [J.M.S.]

2.—In the treatment of several cases of **hyperidrosis of the axilla** Kolipinski has adopted the following routine: The base of the axilla is washed and shaved. Then the **thermocautery** is applied with its flat side, from 10 to 20 times, to the space from which the sweat is seen to ooze, and burns of the second and third degree are produced. A dry bismuth or zinc oxid dressing is applied and the patient may resume his ordinary occupation in a few days. The history of a case is given. [J.M.S.]

3.—Lockyard considers the use of the **eustachian bougie** indicated only in two conditions, viz., **tubal stenosis** and **tinnitus**. This does not include electrical treatment with copper bougies or insulated catheters. After discussing the anatomic structures and situation of the eustachian tube, and especially the folds in the mucous membrane at its lower portion, mentions several methods of employment. These are the use of **graduated bougies** and rubber capsules fastened to the catheter and inflated after their introduction. A case is mentioned of a man, aged 46, who had been subject to increasing deafness in the right ear, combined with subjective noises, and in whom 7 months had passed without a recurrence under the employment of bougies, after many other methods had failed. The dangers are acute otitis media, emphysema, perforations of the membrana tympani, dislocation of the ossicula; aggravation of the existing symptoms and of the local trouble, faintness, and fainting. The results are uncertain, but when beneficial are due either to pressure upon cicatricial tissue or by reflex influence upon the auditory center. [M.R.D.]

4.—The frequency of middle-ear disease in infancy is astonishing. That the ear can be so frequently affected in infancy without attracting attention to that organ is easily accounted for by the fact that the patients are often too young to indicate what they are suffering from. The general symptoms may so far outweigh the local ones that the ear is overlooked in our search for their cause. Then, too, there may be suppurative inflammation of the middle-ear, with little or no pain, and without physical signs, such as redness and bulging of the drum membrane, which are relied upon for the diagnosis of such trouble. This is more apt to occur in infancy, when the eustachian tube is short, thereby allowing pus to escape by that channel, rather than to accumulate or escape through a perforation in the membrana tympani. The frequent presence of adenoid tissue or masses near the eustachian orifice in the throat of infants is another reason why children so often suffer from ear disease. The treatment of cases of middle-ear disease in the early stages is by dry heat and gentle douching of the ear itself with some hot antiseptic solution. If the symptoms continue without perforation, a paracentesis of the drum should be made. The nose and the throat usually require treatment; sometimes, indeed, adenoids require to be removed. The remote or **systemic effects of disease of the ear** are symptoms of meningitis, acute intestinal derangement with cerebral symptoms, septic fever, continued high fever and attacks of bilious fever. [J.M.S.]

5.—Snydacker in discussing the importance of **postoperative treatment**, after removing spurs of the nasal septum attributes failure of relief to the substitution of the original obstruction by the formation of cicatricial tissue after the operation. In cases where spurs have been removed there is sometimes observed the formation of a new mucous membrane which however in functioning power is inferior to the original tissue. **Postoperative granulations** should be

cauterized until they cease to form. The treatment should not be discontinued until the wound is entirely covered by mucous membrane. The patient should be impressed with the necessity of **postoperative treatment**, and the influence it exerts upon the subsequent cure explained to him. [M.R.D.]

7. Sexual Intemperance. JENNIE G. DRENNAN.

1.—Phelps has made a careful study on the dissecting table on a case of lateral curvature of the spine. He found that the superficial erector spinae muscles upon the side of convexity were entirely destroyed by atrophy and fatty degeneration, while those upon the side of concavity were not so much affected. He also found that quadratus lumborum, and the erector spinae of the group of muscles of the deeper layer were entirely disturbed by fatty changes and atrophy on the side of convexity, while on the side of concavity the corresponding muscles, although somewhat degenerated, were not so much so as upon the side of convexity. The fatty changes and atrophy on the convex side were evidently due to the pressure of the muscles by the bending of the bones of the spinal column, putting the groups of muscles on the stretch, whereas the degeneration and atrophy on the concave side were produced by contraction of these muscles and their tendons. When the spinal column bends, producing disturbance of bone and intervertebral cartilage, and by pressure, the ribs are distorted and overlapping, and the muscles between the ribs have been joined by shortening, atrophy and degeneration, it is claimed that a cure of such a lateral curvature is impossible. In order to accomplish a cure, not only must the resistance offered by a wedge shaped bone of the vertebral column be overcome, but the distorted ribs must be rotated in order to cure the curve. The most that can be hoped for at the present time from treatment is to prevent the increase of the curvature, to remove the physiologic curve, and to give the patient strength. This can be partially accomplished under anesthesia by applying tremendous force to the thorax or the spine, either by machinery or by hand, the resisting muscles and fascia being divided by the knife. The patients are then enveloped in plaster of Paris, put to bed and kept there 2 or 3 weeks, after which the operation is repeated. Phelps prefers an aluminum corset as a substitute preparation for many of the braces and corsets now worn in the acute forms of Pott's disease and lateral curvature. [W.A.N.D.]

2.—Spitzka has examined 100 brains of dissecting muscle subjects for the purpose of determining the mesial relations of the inflected fissure. The brains were in formalin and were in a good state of preservation. It was found that in 40 hemispheres of the 200 examined the inflected fissure was wanting. Its absence was symmetric in 6 grades, or 3%, while it occurred 22 times on the left and 18 times on the right-side half. All further data were based upon the 160 hemispheres in which the fissure was presented as equivalent to 100 in 91%. The inflection was situated on a plain caudad of an unmistakable cephalic paracentral limb, while in the remaining 9% this limb had become separated from the main paracentral stem by a narrow isthmus or slight vardum. In all cases, however, the inflected fissure indented and lay partly within the paracentral gyrus. In 63% of all cases there was only one such limb or ramus, binding the paracentral gyrus cephalad. This arrangement occurred a little oftener on the left half than upon the right. In 22% there was an additional ramus, intraparacentral in nature, and probably also in origin,

situated just caudad of the inflected fissure. In the remaining 6% the ramifications and disturbances of fissuration were so varied as not to allow readily of any classification. In the large majority of the hemispheres examined the inflected fissure ended upon a meson as well as upon a dorsum in a simple manner. At times a bifurcated appearance was produced. [W.A.N.D.]

3.—The author's illustrations of the importance of a knowledge of ear disease to the general practitioner are based upon an experience of 35 years. He emphasizes the importance of this knowledge by referring the reader to deaf and dumb asylums, where the havoc wrought by neglected cases of otitis media can be easily seen. Chronic ear disease may prove fatal without the complication of an intracranial abscess. He calls attention to the fact that there are special forms of bacteria which at times pervade in an accumulation of pus in the ear, and which break through all barriers. Bacteriologic examinations therefore of ear discharges are absolutely essential. **Myoclonus** is an early manifestation of an **organized exudate** situated within the cranium, and he believes that this symptom is often erroneously considered by neurologists to be of spinal origin. **Vertigo** is described as consisting of four varieties—gastric or digestive, cardiovascular, ocular, and aural. Thomson concludes his article with a plea to medical institutions to practically train their students in otologic examination and diagnosis. [M.E.D.]

5.—Daly recommends camphor 2 grains, heroin $\frac{1}{2}$ grain, and creosote 1 drop, prescribed in pill form, as a remedy in phthisical coughs which have proven intractable, especially the cough which is hard with scant tenacious mucus and little expectoration. He reports 7 cases in which the remedy was used with success. He remarks particularly the value of the camphor in those cases accompanied by nervous depression. In the obstinate diarrhea of phthisis Daly has found the following combination, in tablet form, to be of service: Bismuth subnitrate 15 grains, guaiacol carbonate 1 grain, heroin $\frac{1}{2}$ grain. The persistent irritability of the stomach has been also greatly relieved by these tablets. [T.L.C.]

6.—In the great majority of dislocations of the **acromioclavicular articulation**, the acromion process is displaced downward and inward beneath the clavicle, the outer end of the latter bone riding on top of the acromion, and the cases are very rare where dislocation of the acromion takes place upward with the clavicular injury beneath the process. This fact is readily understood when the structure of the joint is borne in mind and the character of the clavicular injury received. The dislocation is of sufficient frequency to make it one of the surgical pathological phenomena for which the practitioner must be constantly on the alert. The recognition of the luxation is not difficult, yet it closely resembles a dislocation of the humerus forward. The rotundity of the shoulder will be outside and the projection of the overriding clavicle may be mistaken for the apparent projection of the acromion in the shoulder-joint dislocation. When it is remembered that the shoulder-joint is carried slightly forward and inward; the hand of the injured side may easily be carried to the shoulder of the side when the elbow is on the chest; that by following the lines of the clavicle the normal relations of this body with the acromion are disturbed, the clavicle being on top; that there is no marked fossa upon the head of the humerus and that the projection of the clavicle is fully within one inch within the line of the humerus. The actual condition should be easily recognized. Henrahan regards a case of this accident, and adopts the treatment of reduction and retention of the limited articular surfaces in position until union of the torn capsular ligaments are established. The latter is accomplished by placing a pad on the axilla, a folded towel of heavy texture placed over a broad area at the side of the injury, and a strap 2 inches wide is drawn across the shoulder and under the elbow, a pad of absorbent cotton producing a great pressure on the elbow. The strap is drawn as tightly over the shoulder as the patient can bear. [W.A.N.D.]

7.—Drennan believes that **sexual intemperance** is not to be considered as a minor form, and that it is generally ignored, in comparison to liquor and other forms of intemperance, and that the abuse of the sexual act is wrongly shielded by matrimonial bonds. [M.E.D.]

5. The Clinical Value of the Heart Reflex. ALBERT ABRAMS.
6. A Case of Perforating Gastric Ulcer. A. B. ATHERTON.

1.—Clement Cleveland discusses **postoperative intestinal obstruction** and the methods for its relief. He refers here, not to the adynamic type, due to intestinal paralysis from peritonitis, nor to that due to opium, but to those forms of intestinal obstruction which occur from the handling of the intestines during the operation. The peritoneum, a most sensitive and delicate membrane, causes the excretion of plastic lymph upon irritation, and adhesions are very apt to form as a result of this. Speaking of the measures for its prevention, he advocates placing patients in the Trendelenburg posture during the operation. He advises protecting the intestines with the omentum, as far as possible, and covering them carefully with wet pads of gauze and forcing the intestines into the upper abdominal cavity. He also mentions favorably the present custom of surgeons in leaving the cavity partly filled with decinormal salt-solution, which serves, by its rapid absorption, rather better than an intravenous infusion of the same solution. It may also lessen the amount of plastic lymph thrown out, and thus lessen the possibility of adhesions. He quotes 5 cases in which the insufflation of oxygen has been used for the relief of postoperative obstruction. Oxygen is administered per rectum, and great relief has followed its use. The writer believes that this acts not merely by the power of straightening out the intestines and opening the lumen, but serves as a stimulus to peristalsis. Four of his cases were desperate ones, and the insufflation made the difference between life and death. Oxygen used by the bowel must be absorbed to some degree and enter the general circulation, serving in this way as a stimulant and tonic, but Cleveland has used it solely for its mechanical effect. [T.L.C.]

2.—Peabody describes the case of a man of 34, who had for 11 years lived in New York City and had been nowhere else during that time excepting in Pennsylvania. He had daily attacks of severe headache subsequently accompanied by severe abdominal pain in the neighborhood of the umbilicus radiating toward the left kidney. The pain was greatly relieved by vomiting; the condition had become so distressing as to lead to great reduction of health. The spleen was increased in size, was hard, was tender to pressure, but did not move with respiration. Examination of the blood showed malarial crescents. The use of quinin brought about entire cure and the spleen subsequently became immovable. The abdominal pain was considered to be due to adhesions of the spleen to the diaphragm. Traction upon this when the spleen was increasing in size under the influence of malarial poisoning was thought to have caused the pain. [D.L.E.]

3.—Stoner gives a general review of digestive processes, noting that primary digestion in the stomach is incomplete, that the chief part of digestion and particularly of absorption takes place within the small intestine, and that the facility of absorption is dependent upon the vitality of the cells of the intestinal mucosa. He notes the unfavorable influence of gastric hypochlorhydria upon intestinal digestion, and the similar influence of glutony. The most prominent symptoms of intestinal indigestion are distress and abnormal fullness in the hypogastric or gastric region without definite tenderness. There is a constant desire to eructate, but the stomach is found to contain no gas. There is flatulence and usually constipation, and the urine may contain a trace of bile with excess of urates and indican. There is often marked depression of spirits. There is intolerance of starches, fats, sweets and wines. Treatment consists chiefly in prohibition of the latter forms of foods. Lean meats should be allowed in moderate quantities. Antacids are useful. [D.L.E.]

4.—The remarks which Sherwell makes are chiefly that topical applications are usually used too strong in the treatment of skin affections of children, and may have very damaging results. Even vaseline is frequently irritating, particularly in children. In relation to food and clothing, he considers that children of various ages, particularly infants, are frequently overfed, and fed too frequently; they are also commonly clothed too warmly, particularly in summer, and this irritates the skin. The fear of washing eczematous areas is also something which he considers silly. He recommends a gentle washing once daily with water made slightly alkaline with borax or soda, and bran bag. In older children it is often necessary to stop the use of tea, coffee, and a large variety of indigestible foods, and salines are often valuable. The skin usually needs soothing treatment. [D.L.E.]

5.—The heart reflex is best determined by the use of the fluoroscope. After irritating the skin over the heart by various means, best by active rubbing with a lead eraser, the size of the heart shadow may seem to grow much smaller. This may be determined upon percussion also. A portion of the decrease in size is due to the lung reflex, which consists in dilation of the lung, thus partially covering the cardiac dulness. This latter factor soon disappears and then the cardiac dulness may be found much smaller than previously, and this is due to actual contraction of the heart itself. Abrams thinks that it is this skin-irritation which produces the greatest effect in the Schott baths, and he has found direct irritation of the skin over the precordia valuable in the treatment of cardiac dilation, and considers it also a valuable sign in the differentiation of dilated heart from pericardial effusion. [D.L.E.]

6.—The case reported occurred in a man of 62 who was operated upon 10 hours after the occurrence of perforation. An opening the size of a lead pencil was found on the anterior surface of the stomach, near the pylorus. The perforation was closed by two rows of Lembert sutures. The man did fairly well for about 3 weeks, when he vomited some dark liquid with blood in it. After this his recovery was continuous. He died, however, about a year afterwards, of lung trouble it was said. [D.L.E.]

1. A Study of 81 Cases Operated upon Under Analgesia Obtained by Subarachnoid Spinal Cocainization. GEORGE RYERSON FOWLER.
2. The History, Aim, and Purpose of the Medical Societies of the State and Counties of New York. FRANK VAN FLEET.
3. Pneumonia: Its Etiology and Treatment. D. L. BURNETT.
4. On the Prognosis of Hysteria: A Contribution to the Question of Fatal Hysteria. JOSEPH FRAENKEL.

1.—Fowler believes that the delay in the employment of subarachnoid spinal cocainization is due to the favorable results that have been given by other anesthetics when properly administered. The author's experience of this form of anesthetics comprises 81 cases which have been divided up as follows: Operations involving the peritoneum, 26; operations in the pelvic region not involving the peritoneum, 34; operations upon the lower extremity, not included in the above mentioned cases, 13; amputation, 5. In the 3 cases of inguinal hernia there was pain when the areas supplied by branches of the ileoinguinal and ileohypogastric nerves were attacked. In a case of acute appendicitis, handling of the inflamed appendix gave rise to such pain that a general anesthetic had to be administered in addition to the spinal one. In 2 cases of varicocele, pain was produced by handling the cord, and general anesthetics had also to be administered in addition to the spinal anesthesia in a case of anterior colporrhaphy and perineorrhaphy. In one case the patient hearing the call of a surgeon for the second knife, after a previous absolutely painless procedure, was very sensitive to the slightest touch thereafter. He believes that the technic of the lumbar puncture is not as simple as might be supposed. In stout individuals the spinous processes are difficult of palpation, and even in cases where there was not considerable fat a patient that was very nervous when placed in a direct posture would throw the muscles

into such rigidity as to render it almost impossible to fix the point of the spinal process. Unless the lumen of the needle had become occluded in its passage through the soft parts, cerebrospinal fluid flows without any difficulty. In some cases aspiration either with the syringe that is being employed or a special suction will still more facilitate the outflow of the cerebrospinal fluid. He generally allows a full minute for the injection, thus giving ample time for the solution to thoroughly mix with the cerebrospinal fluid. The solution should be freshly prepared with a menstruum of sterilized water and boiled for a full minute before using. It is believed that a concentrated solution of a definite quantity will not produce disagreeable symptoms any more than the same dose in a diluted solution and that the effect will last longer. The result seems to have been affected but little as far as the position of the patient was concerned during the injection. Analgesia is present in the soles of the feet from 1 to 5 minutes, and in from 5 to 15 minutes extends to the umbilicus. In none of the author's cases did he fail to reach the umbilicus when the solution proved at all effective; in 2 cases it reached to the vertex. In none of the cases did the analgesia subside below the umbilicus under 27 minutes. The amount of cerebrospinal fluid present in each case has probably direct bearing upon the extent of the analgesia. With a reliable solution it is believed that a failure to produce analgesia depends upon the failure to introduce the solution into the spinal cord. In the greater number of cases disagreeable features were present, among them being vertigo, nausea, vomiting, headache, chills, elevation of temperature and increased pulse-rate, pallor, cold sweat, and involuntary urination and defecation. The case of Tuffier in which death occurred was found upon a postmortem examination to have been affected with cardiac and pulmonary lesions. Such complications, however, have been disregarded by the author in experimenting with this anesthetic. In some cases there were even heart-murmurs present, and in one case there was gangrene of the lungs. The author considers that insensibility to the surgical procedure is not all that should be required of an ideal anesthetic, and that on the other hand such features as the knowledge by patient of what is taking place around him and the perception of the gravity of the operation are to be distinctly avoided. A further trial and conscientious study of a large collection of cases is still required to ascertain the danger that may accompany employment of this form of anesthesia. [M.R.D.]

2.—Frank VanFleet gives a historical resumé of the medical societies of the State and County of New York from their inception in 1806. He also takes up with considerable detail the rupture of the societies from the American Medical Association on account of their unwillingness to subscribe in full to the ethics of the American Medical Association with a special reference to consulting with those who practise exclusive dogma. [T.L.C.]

4.—Fraenkel discusses the prognosis of hysteria, and reports 4 fatal cases. He divides hysterical conditions in 3 separate groups from a clinical point of view, and remarks that these are not fixed by strict boundary lines and can show many interchanges and mutual displacement. First, the predominantly mental forms, hysterical psychoses with more or less pronounced somatic symptoms. Second, predominantly cerebrospinal forms; symptoms of this group are mainly composed of phenomena of irritation, or paralysis of motor or sensory nerves. Third, predominantly splanchnic forms, the symptoms of which are mainly phenomena of irritation of the motor or sensory apparatus supplied by the splanchnic or sympathetic nervous system. Around these 3 groups is wound the symptom-complex of hysterical seizures—grand ou petit mal hystérique. He believes that the prognosis in the first 2 groups is more favorable than the third, in which his 4 fatal cases were classed. [T.L.C.]

3. The Differential Diagnosis of Intestinal Obstruction. Z. BOYLSTON ADAMS.

1.—Beyer reviews the experimental work of Kocher and others in regard to the effects produced by rifle bullets, and then shows, by reviewing the experience of surgeons in the Spanish-American and Anglo-Boer wars, that the damage done to the human body by the modern bullet confirms the work of the experimenters. Recent experience show the proportion of killed and wounded to be about the same as in the past—one to four—but of the wounded many more now recover, due to septic and antiseptic treatment. Kocher showed experimentally, and experience has confirmed it, that, the “explosive” effect of bullets is due, not, as was formerly supposed; (1) “to deformed and deforming bullets; (2) to indirect or ricochet shots; (3) to the rotation of bullets; (4) the melting of the lead of the bullet;” but that this effect is in proportion to the **velocity** of the bullet. The bullet develops its greatest velocity a few feet from the gun, after that it gradually decreases until it reaches the ground. In firing bullets through glass plates Kocher found that “a 10 mm. lead bullet and a 7.5 mm. steel bullet, moving alike at a velocity of 595 m., produce like effects.” In experiments on tin cans filled with marbles he found that the same amount of explosive effect was produced by hard bullets fired from smooth-bore guns as by lead bullets from rifles, provided they possessed the required velocity. This does away with the old idea that rotation or deformable bullets were required to obtain lateral or explosive effects. “Kocher’s explanation of the nature and production of the lateral or explosive effect is, that the energy of the bullet is transmitted from the parts struck, first, in the direction of the line of fire; next, with increasing velocities, in a funnel-shaped direction towards the exit, and, lastly, with still greater and the greatest velocities, in all directions.” Experiments with cans filled with water or substance saturated with it, went to show that the more liquid the contents of the vessel the greater was the lateral or explosive effect, which was increased with increase of the velocity, regardless of the kind of bullet used. Experiments with the water box showed that leaden bullets made greater penetration under lower than under higher velocity. A leaden bullet creates its own resistance in the water—the higher the velocity the greater the resistance. From the moment the resistance reaches a point so as to cause deformity, explosive effect also becomes apparent. From that time on the effect is increased with the velocities used, and at last it results in the bursting of the box and in the water spurting up to the height of 10 feet. He concludes, “that the destructive effects of our modern high velocity bullets upon organs containing a large percentage amount of fluid are produced by hydraulic pressure.” Salzman and Kocher agree that the enclosing capsule is not necessary to the explosive effect from hydraulic pressure, but, that this and the deformed and deformable bullets increase the effect, which is most of all dependent on the velocity of the bullet. The loss of velocity in penetrating different aims is dependent on the hardness of the bullet and its caliber, and the large part of the loss of velocity being converted into lateral or explosive effect. The reduction of the caliber of the bullet and the hard metallic jacket has resulted in making small skin wounds and lessening the hydraulic effect in soft parts at close range, but the injury to the bone remains much the same as from the old bullets. It is not unusual to find a small wound of entrance and exit and overextensive damage of soft bone, as of an epiphysis, for instance. Many favorable prognoses were made during the late war because of the small wounds of entrance and exit, and yet many of these patients are now invalided from service from extensive subcutaneous injury, resulting in the deposition of large amounts of callus or extensive adhesions of muscles, etc. Sir William MacCormac attributes the benign character of many of the abdominal wounds in South Africa to the fact that in most instances the alimentary canal was empty and, therefore, the hydraulic effect was at a minimum. Since the “amount of destruction experienced by any part of a bone depends principally upon the amount of resistance which it opposes to a bullet,” Beyer argues that bone injuries from bullets should be classified according to Kocher, as of the epiphysis, the diaphysis, or of the metaphysis, as the resistance offered by these parts differs so much. He objects to

the term “expansive” and thinks “explosive” the proper word as describing the lateral effect of a bullet. “The highest velocity shots upon skulls, filled with brain, show that they are attended by a high degree of explosive or hydraulic action.” Nerves and bloodvessels sometimes show remarkable escape from injury even with the modern bullet, but only when velocity is low. An undeformed modern bullet passing through a lung even at the highest velocity shows better lateral action. [J.H.G.]

2.—Edes considers those spinal degenerations not usually recognized as belonging to the well-marked system-diseases and which are accompanied by states of malnutrition of the blood. He cites 4 cases illustrating this class of degenerations with the results of one necropsy. The general symptoms presented by such cases are those of severe anemia, weakness of motion and coordination (rather than especial groups of muscle-paralyses). At first the deep reflexes are apt to be exaggerated; later there may be absolute paralyses, extensive anesthesia and loss of deep reflexes. The sensory symptoms include numbness of the extremities, inability to use the hands for fine work, and sense of coldness in the lower extremities. The notes of the partially incomplete autopsy given state that to the naked eye the brain seemed normal and was not examined further, except the medulla in its lower portion, and some sections of the cord. The author concludes that the degeneration in this case would seem to follow the system-fibers, unlike the majority of such cases, in which there is a tendency to the formation of focal lesions. [T.L.C.]

3.—Z. B. Adams discusses the general causes of intestinal obstruction and quotes a list of 56 cases, which in 27 was diagnosed incorrectly. He presents certain important points in the differentiation of the various conditions. First, between **obstruction** and **dysentery**; second, between **chronic** and **tuberculous peritonitis**, especially in young subjects. He states that the most important differential diagnosis lies between **strangulation** and **impaction**, or occlusion of the lumen, whether from within or without. He abjures the use of **opium** or purgatives before the diagnosis is made and insists upon routine examination by the rectum and the persistent use of high injection as valuable aids in making the diagnosis. He points out that **celiotomy** in experienced hands is a comparatively harmless operation, which has undoubtedly saved many lives. [T.L.C.]

2.—Flexner, discussing the classification and etiology of dysentery, sums up our present knowledge by stating: (1) That no bacterial species yet described has the especial claim of being regarded as the chief microorganism concerned with the disease; (2) it is not likely that any bacterial species normally present in the intestine or environs of man, except where the disease is endemic, can be regarded as the probable cause of epidemic dysentery; (3) the relations of sporadic and epidemic dysentery are so remote that it is improbable they are produced by the same cause; (4) the pathogenic action of the *Ameba coli* in certain examples of tropic and sporadic dysentery has been disproved by the discovery of the *ameba* in the normal intestine. *Ameba* are commonly present, and are concerned with the production of the lesions of subacute and chronic dysentery. They

have yet to be shown to be equally connected with the acute dysenteries, even in the tropics. Shiga has made a careful bacteriologic study of Japanese dysentery. From his cases examined a bacillus was isolated which fulfilled the requirements of a causative agent of this form of dysentery. Flexner, during 3 months' residence in Manila, carefully studied the dysentery of the Philippine Islands. He describes two main forms of the disease, acute and chronic. Ameba were not found in the stools. In chronic, ulcerative forms they were variable in number. Upon bacteriologic examination Flexner isolated two types of organism found especially in the acute cases. The first organism is a bacillus, somewhat of the colon-typhoid type, with peculiarities of growth described. This gave the agglutination test many times with the blood of persons suffering from the disease, whether the host or another individual. Type 2. Present in all cases. Its properties agree with that of *B. coli communis*. With this organism the agglutination test was frequently positive with the host and rarely with other individuals. This organism was found to be absent from healthy dejecta or in the stools of the natives suffering from beriberi. Flexner concludes this bacillus to be identical with that described by Shiga. The results with the agglutination test were positive in cases of the acute disease in which infection with the bacilli was established. It was also present in a case of Porto Rican chronic dysentery, but was inconstant with blood from other chronic cases. With several cases of chronic amebic dysentery under Osler's care the test was negative. As to treatment, Flexner expects great benefit from a species of vaccination and witnesses the effect of injecting the dead bacilli in cholera. The method and details will have to be carefully evolved. [T.L.C.]

3.—Musser reports a fatal case of Porto Rican dysentery occurring in a soldier of 32 years. The pathologic findings indicated dysentery, ulcerative and pseudomembranous colitis, possible infarction of the lung and a universal anemia. A positive test was obtained with cultures of the bacillus of Shiga—a point of value, since the case might have been mistaken merely for one of aggravated scurvy, the inter-currence of which occurred during the period of observation. The course was afebrile. There was extreme emaciation, strikingly sallow skin and a profound toxic state terminating in the typhoid condition. Bacteriologic examination revealed the presence of an organism corresponding with the *Bacillus dysenteriae* isolated from cases in Manila. [T.L.C.]

4.—N. S. Davis, Jr., reports a case diagnosed as malignant endocarditis. The patient had for 7 years following an attack of grip failed perceptibly in health and came to the hospital suffering from headaches and gastric disturbance with occasional attacks of dyspnea. Examination on admission was negative save a slight epigastric tenderness. Under treatment the gastric symptoms subsided. Then fever was observed, which for a few weeks indicated a typhoid curve. The spleen became moderately enlarged, but plasmodia were not found, nor was the Widal test positive. After the first week there was a gradual decline in temperature. At this time a marked weakness of the first heart-sound was observed and a roughening of the second aortic sound. This roughening gradually developed into a distinct murmur. The patient then suffered from two severe chills followed by profuse sweating and a third cold stage but no distinct chill. Up to the time of the first chill the patient had been treated by the Brand method. The chills greatly reduced the patient's general condition, which appeared desperate. Unguenti Credé was now employed and a gradual recovery followed. The aortic murmur disappeared, but the second sound remained rough. The diagnosis seems to have been made upon the exclusion of typhoid, malaria and tuberculosis and the septic character of the temperature at the time of the chill, as well as the cardiac symptoms with the disappearance of the aortic murmur with convalescence. The urine contained but a trace of albumin, the leukocytes were normal and there was no report of a bacteriologic examination of the blood. The diazo reaction was positive. There was no history of septic emboli; an intercurrent phlebitis recovered promptly. An incomplete list of reported cases of recovery from malignant endocarditis is added. [T.L.C.]

5.—Wills advocates external drainage of the lung-abscesses as conservative surgery and reports two cases operated upon for this condition. The first case was a man, 45 years of age, and muscular. When first seen he had a cavity in the

left lung extending from the sixth interspace to the ninth rib and apparently from the spinal column to the midaxillary line. The patient gave a history of dyspnea with vomiting of from a half to one pint of pus every morning. Examination of his sputum showed the presence of tubercle bacilli; he also had septic temperature. External drainage of the lung advised but declined. Six months later the patient returned for treatment; condition much worse; had lost a great deal of flesh. He was expectorating large quantities of pus continuously. Examination of chest showed evidence of inflammation of chest wall extending over the fifth, sixth, and seventh spaces, from the anterior axillary line forward to and below the left nipple. This area was red, painful, and presented all the signs of a suppurating focus. The supposition was that the abscess had ruptured into the pleural cavity, and was approaching the surface. The patient's general condition was very bad. An inch and a half of the sixth rib was resected, pleura found thickened, but when opened contained no fluid; lung congested. Patient's condition became so precarious that operation was stopped; rubber drainage tube inserted in the pleura; wound closed. Ether anesthesia; patient reacted from operation with some difficulty. Nine days after the operation the patient was suddenly seized with a fit of coughing, and a sudden gush of pus poured from the mouth and at the same time poured through the drainage-tube from the wound. Profuse discharge from the wound kept up, requiring frequent dressing. Bichlorid solution 1:4000 was used twice daily in irrigating the cavity; patient showing no physiological effect of the drug from its use in this way. The patient was able to taste the irrigating fluids. The patient went home, took care of the wound himself, washing it out with bichlorid solution. Eighteen months after the operation the patient was practically well; no cough, gained flesh, was able to do manual labor. The second case was a man, aged 30, not very robust. Examination showed a cavity which extended from the end of the scapula as far down as the last rib and from 2 inches of the spinal column to the midaxillary line on to the right side. No expectoration of pus. Temperature varied from subnormal to 103° F. Operation advised. Ether was administered. Two inches of the eighth and ninth ribs were resected. The pleura found healthy and empty. Patient's condition became so bad that the operation had to be stopped. The wound was closed. Six days after the operation, wound perfectly healed, but skin distended. Fluctuation was noticed. Wound was opened, and nearly 2 pints of brownish, fetid pus gushed forth. On digital exploration, the finger entered directly into the lung cavity. The pleura was adherent to the edges of the wound so that its cavity was not implicated. After this, temperature remained about normal. Patient's condition improved. Within a month following the operation, the patient was coughing up pus and tasted irrigating fluids. Patient has not improved since. The abscess cavity is still discharging a small quantity of pus. He calls attention to the fact that both the patients took ether badly and almost collapsed on the table. [J.H.G.]

6.—Beck calls attention to the fact that a Röntgen-ray picture is by no means an ordinary photograph of an object, but a silhouette only, and to interpret such properly, a thorough knowledge of anatomical conditions and relations must be had. This is particularly true of bones; those of the carpus and tarsus being especially hard to understand. He gives instances of supposed fracture about the wrist and ankle where the supposed fracture was due to denseness of shadow produced by some of the small bones. The greatest diagnostic difficulties are offered by the joints. The more complicated a joint is, the greater the difficulty in understanding a skiagraph of its various positions; this is especially true of the elbow and hip joints. The older the fracture is the less conspicuous the fracture-line will appear, being more or less overshadowed by callus. Hence, if a case fails to be skiagraphed shortly after the injury, no evidence of the fracture may be subsequently obtained. Callus formation on the other hand may be so abundant that, in spite of the absence of displacement, the fullest evidence of fracture may still be furnished months after. In supposed fractures involving joints, a skiagraph should also be made of the corresponding healthy articulation. In studying skiagraphs of the bones and joints of children, he urges the necessity of the knowledge of the time of their ossification. He also urges making the skiagraph of more than one position and

illustrates this necessity by recalling a case of oblique fracture of the tibia in the middle third, a skiagraph of which, taken from before backwards showed no evidence of fracture, but one taken from side to side showed the fracture very distinctly. Skiagraphs of foreign bodies vary in size according to the distance from the tube, and in skiagraphing oblong bodies great errors as to their extent may be committed. Mechanical and chemical errors must also be considered. [J.H.G.]

7.—Deaver discusses, under this heading, appendicular abscess. Opening and draining an appendix abscess does not insure the patient immunity from subsequent attacks; in fact, recurrent attacks are more likely to follow a partial operation on account of the retention of a diseased appendix. He does not believe that in the case of the walled-off abscess, the appendix is "frequently discharged as slough." Few abscesses are completely walled off. Many cases are lost by postponing operation 24 hours; but few, if any, by too early surgical interference. He says he knows but two things in a case of appendicitis: that the appendix is inflamed and that it should come out. To foretell the extent of the disease is impossible. He divides abscesses of the appendix into 5 varieties: 1. Postcecal, or postcolic, the pus being formed between the layers of the mesocolon; it is walled-off, but not so walled-off as to avoid infection of the peritoneum during its evacuation. He does not approve of draining such collections through the loin space. 2. Where the pus is found directly beneath the parietal peritoneum, being limited by the cecum, coils of small intestines, the omentum, the appendix, the parietal peritoneum, and masses of lymph binding these together. In this form a communication with the pelvis is frequent. 3. The collection of pus is confined to the pelvis and shut off from the general peritoneal cavity. The evacuation of such an abscess from the vagina or rectum is heartily condemned. 4. This variety is found located near the median line of the abdomen and the inner side of the cecum. The retaining wall being composed of cecum, appendix, small intestine, mesentery, omentum, and the sigmoid flexure of the colon. In this variety of walled-off abscesses it is sometimes necessary to make a second incision to protect the peritoneal cavity. 5. In the last variety of appendicular pus, there is no attempt on the part of nature to confine the pus. It is the most unfortunate variety, and if the patient is not operated upon immediately, the chances of recovery are reduced to nil. He then instances a case of an interne at the German Hospital, who was taken sick with abdominal pain on September 30; started to work the next day, but was obliged to return to bed with recurrence of pain at noon. At 1 o'clock he was operated upon, and the abdominal cavity was found filled with serofibrinous exudate, and the appendix distended with pus. Recovery was interrupted. He gives the mortality of operations done in the presence of pus as from 10 to 18%, while in the presuppurative stage the mortality is 5%. "There is no choice as to the time of operation in appendicitis." He urges operation as soon as diagnosis is made. He closes with the following conclusions: 1. Pus is an avoidable complication in the treatment of appendicitis. 2. The patient's welfare is best preserved by avoiding any of the complications incident to pus-formation. 3. The walled-off abscess is not the blessing to be sought, but rather an evil to be avoided by prompt surgical interference as soon as the symptoms of appendicitis manifest themselves. 4. Operation on cases of walled-off pus imperils the patient's chances for recovery, on account of liability to infection of the peritoneal cavity. 5. Fecal fistula, as a result of a walled-off appendicular abscess, is an unavoidable sequel to appendicitis, and should not be permitted to occur. The latter statement is true of all complications and sequels of appendicitis due to pus-formation. [J.H.S.]

8.—Lyster says that as troops were sent out from Manila post-hospitals were established at regular intervals along the route. Base-hospitals were converted out of public buildings in the small towns which were most accessible to Manila. At Manila there are large general hospitals, one containing as many as 1,400 patients at one time. To this hospital are sent patients from the crowded base-hospitals. There are also a number of hospitals for the treatment of special diseases; for surgical cases; for those convalescing from malarial fever; for medical cases and all diseases of the eye; and for soldiers who are to be sent to America for treatment. From this

latter the patients are transferred to the general hospital at San Francisco. Contagious diseases are looked after by a special board of investigators. Medicines, foods necessary for the sick, instruments, and even ice, are now promptly supplied to sick soldiers, and it is hoped to equip each base-hospital with an ice-machine. There is a school of instruction for the hospital corps, men giving them instruction in the handling of injured and also in the nursing of the sick. Two hospital ships are under the orders and immediate control of the medical department, one having a capacity of 260 beds. Several small light-draft vessels could be used with advantage in removing the sick from points along the more shallow streams. The only railway in Manila is supplied with two special cars, fitted out with cots. A surgeon accompanies each trip. A difficult problem in Manila is public vaccination. The American soldiers have been remarkably free from smallpox because of the frequent vaccination at home; but with the natives it is far different, many showing the signs of the disease. Prejudice and ignorance here interfere with vaccination as they do in America and England. Vaccine farms have been established in Luzon, the lymph being procured from the caribou. In this manner the vaccine can always be had fresh. The medical department has done a great deal to improve the hygiene of the cities and towns throughout the island. The efforts of the department have resulted in limiting the bubonic plague to a marked degree. It has been prevalent in Manila for several months, but no cases have been heard of outside of the city limits. The use of the odorless excavator has been introduced into Manila. The inspection of the abattoir, of the markets and the foods for sale in them, are duties which develop on the medical officers. The house and person of the native Filipino are remarkably clean, but he is indifferent as to his surroundings and whence his water supply comes. Typhoid is endemic in the islands, and garrisons have to be most careful in the selection of their water supply. Leprosy, probably introduced from China, has spread until there are in Northern Luzon some 12,000 natives and Chinese afflicted with the disease, and so far it has been unrestricted. A special commission is searching for an island on which to establish a leper colony. [J.H.G.]

9.—Amberg describes a normal acoumeter. The instrument consists of a steel ball of given weight falling at a given distance on a metallic block. The instrument is considered to be of value on account of the accuracy that can be obtained, independent of the dissimilarity in the voices of individuals. [M.R.D.]

10.—Stieren reports a case of amblyopia following the intoxicating use of Jamaica ginger, with subsequent recovery of vision. The patient was a contractor who, when first seen, was totally blind. After a heavy debauch, being unable to obtain liquor of any kind, he consumed about 12 ounces of Jamaica ginger. This was followed by stupor, total blindness and excessive thirst. Upon examination there was found extensive mydriasis, unaltered by light or accommodation. The media were clear and no change was seen in the disc beyond a slight haziness of the edge, due to slight retinal edema. V. = perception of moving hand at 12 inches. The cornea was almost entirely anesthetic. The vision improved progressively under hot footbaths, compound jalap powder, and pilocarpin hypodermatically. [M.R.D.]

12.—Holt, in discussing the application of the douche in the treatment of ophthalmia neonatorum, believes that this mode of therapy fulfils the requirements of cleanliness which are so essential in this disease. He describes a critical case that had been treated by the usual methods, such as ice compresses, silver nitrate, etc., and which recovered under systematic irrigations by means of the douche, the solution employed being 1% of boric acid. The same fortunate result has been obtained in other cases of the author by means of this method when other well known methods had failed. In the first case extensive involvement of the cornea was believed to have been present. [M.R.D.]

8. A Further Contribution to the Study of Full-Term Ectopic Gestation. EDWIN B. CRAGIN.

1.—Baer reports a case to illustrate the relative advantages of vaginal and abdominal section. The patient, a woman of 30, presented urgent symptoms of pelvic suppuration and septic intoxication, with a hard tumor in the right iliac region. Her condition making an abdominal section too hazardous, the pus was evacuated by vaginal incision. This relieved the acute symptoms, the patient's condition improved, and 19 days later an abdominal section was made and the tumor was with difficulty enucleated from its attachment to the uterus and its many adhesions to intestines, and removed. Complete recovery resulted. [W.K.]

2.—Harrison, in this contribution to the study of pelvic hematocele, agrees with Fehling in his estimate that in 95% of the cases, hematocele is due to a tubal pregnancy, and that incomplete tubal abortion with a resulting hematocele constitutes the most frequent termination of such pregnancy. In tubal abortion that causes hematocele, the tubal tumor is first of all hard, because coagulated blood dissects its way between chorion villi and tube. Hardness, in fact, is proof of the death of the fruit. The blood-sac develops gradually, accompanied by the symptoms of pain of a more or less paroxysmal character, and the discharge of blood per vaginam at irregular intervals, and of a dark color. In such cases the indications for operative interference would seem to be clear, unless absorption occurs rapidly and there is no serious disturbance of the health. The operation to be preferred is laparotomy, its advantages being that you have a more complete survey of the field of operation, can decide with certainty as to what is diseased and what not, and are better able to control the hemorrhage. Moreover, convalescence is much more rapid, as a rule, and pus-formation and the retention of pus are not likely to occur in laparotomy. [W.K.]

3.—Bovée says that although statistics are not available, there can be no doubt that injuries to bladder and ureters are more frequent in radical surgery for cancer of uterus than in ordinary hysterectomy, as the dissection is so much wider, embracing, as it does, removal of tissues surrounding the ureters and bladder, while in the ordinary hysterectomy for benign conditions one scarcely sees a ureter. Also these injuries are more frequent in vaginal than in abdominal hysterectomy. Prevention of such injuries is of the first importance, but Bovée considers Kelly's plan of placing sounds or catheters in the ureters and leaving them there during the operation as inadvisable; because of the extra strain on the strength of the patient incident to the necessary manipulations. He prefers to isolate the ureter except from the peritoneum early in the operation, then it can be brought into view and its injury avoided. If the ureter be occluded by a ligature, cut the ligature and religate the other tissues if necessary. If it be compressed by a forceps, resection may be necessary; but usually the reparative power of this duct can be relied upon to overcome the condition. Longitudinal or partial transverse incisions should be sutured at time of operation. Complete transverse section will require anastomosis with itself if high in the pelvis and with the bladder if in its lowest 2 inches. In bladder-punctures or incisions immediate closure with permanent bladder drainage for a few days will usually suffice. In late bladder sloughs and bladder injuries discovered after operation, a second operation is usually needed, though frequently permanent catheterization cures. [W.K.]

4.—Clark reports an unique case of sarcoma of the uterus with fibroma of round ligament occurring in a woman aged 59. Sarcoma of the uterus is very rare, only 154 cases being

on record. The one here reported was a sarcoma from its inception and was on the uterine wall. In view of the fact that careful examination of the bloodvessels showed no traces of round cells sowing blood infection, the prognosis is extremely favorable. This case is quite unique and a similar one may not occur in 1,000 cases. The 2 types of tumor were quite distinct, and one could make out without the slightest trouble the pure round cell sarcoma and the fibroid tumor. [W.K.]

5.—Stahl reports a case of fibromatous tumor in labor. The tumor was a pedunculated fibroid springing from the cervicocorporeal junction, producing at one time great pain and serious reflex disturbances from pressure against the superior strait to the right anteriorly, and was first seen in the fourth month of pregnancy. The acute symptoms were relieved by palliative treatment, the pregnancy continued through the seventh month when premature labor was induced by climbing high steps in very warm weather. The labor was normal and a well-developed 7 months' fetus was spontaneously delivered, but it succumbed 6 hours after birth. The puerperium was normal and Stahl is of the opinion that the patient can now stand the operation of the vaginal enucleation far better than at the fourth month. [W.K.]

6.—Talley reports 2 cases, one of which was an instance of gonorrheal salpingitis with coexisting pregnancy, in which the pathologic study showed advancing gonorrheal infection, proceeding from the fimbriated end of the right tube toward the uterine cornua; in the second case, an ovarian cyst had been carried high in the abdomen by the pregnant uterus, forming an attachment to the liver, and giving symptoms immediately after delivery through the shrinkage of the uterus and tension on the pedicle. [W.K.]

7.—According to Weeks the cause of ophthalmia neonatorum is usually the gonococcus of Neisser, and the treatment should be: 1. Mechanical. The conjunctival sac should be cleansed frequently, the more so because of the absence of tears. This should be effected by the employment of a nonirritating aseptic or mildly antiseptic solution. Many consider a 3% solution of boric acid as most desirable for this purpose. 2. The conditions for the development of the microorganism should be made as unfavorable as possible; this can best be done by reducing the temperature of the conjunctiva. This is comparatively easy by the application of little cold pads changed every 1 or 2 minutes, and in the acute stage used from 1 to 4 hours, 3 times daily, but discontinued as soon as the swelling of the lids subsides. 3. The destruction of the microorganism as far as is possible by the application of a germicide to the surface of the conjunctiva. Weeks uses a 1% solution of silver nitrate, applying it once a day after removing all secretion from the conjunctiva. 4. Constitutional treatment, which should be directed to the general improvement of the child's condition. [W.K.]

8.—Cragin reports a second case of full-term ectopic gestation in which the child was delivered alive; and he believes that the viable ectopic fetus is worth saving; that within certain limits attempts to save the child do not seriously increase the mortality or morbidity of the mother; hence in the treatment of full-term ectopic gestation the child should receive more consideration that it at present enjoys. [W.K.]

1. Spiritus Saponis as a Hand Disinfectant. An Answer to "Correction" of Paul and Sarway. F. AHLFELD.
2. Vaginal Infection. An Open Answer to Dr. Kronig's "Remarks." F. AHLFELD.
3. An Early Indication of Ascites. L. LANDAU.
4. A Jointed Phantom for Demonstration in Obstetrical Instruction. LUDWIG KNAPP.

1.—In answer to the conclusion of Paul and Sarway that hot water and alcohol would not disinfect the hands, Ahlfeld replies that in his experiments with spiritus saponis, as advocated by them, the results do not compare in efficiency with those obtained by hot water, soap and alcohol (76-96%) and that alcohol, although much diluted, is the effective agent in the disinfection by spiritus saponis. [W.K.]

2.—Abfeld quotes a series of experiments to show that of 38 tests, in 28 cases the hands were made germ-free by means of alcohol, so that in scraping them no germs could be obtained which would develop in culture media, and that in 22 of the 28 cases the hands were still sterile an hour afterward. Hence as a practical result of these experiments he concludes that contrary to Kronig's opinion, we can undertake, not only a mere examination, but a long-continued obstetrical operation without fearing that the field of operation will in this time be infected by germs set free from the hands. [W.K.]

3.—In Landau's opinion it is very important to recognize the existence of ascites in its early stages, and he shows how to make the diagnosis before the disease is far advanced. When the measure of fluid in the abdomen is small, it is impossible to grasp around the uterus while the patient is lying in the ordinary horizontal position, since the somewhat drawn back uterus presents to the fingers the feeling of lying on an air or water cushion. But if the patient be placed with flexed thighs and knees, as the pelvis is elevated the conditions are completely changed, the water recedes to the diaphragm and the palpating fingers now touch each other around the uterus. The bladder must be carefully emptied before the examination. As the disease advances and the amount of fluid increases, naturally the difference of palpation in the two positions is diminished, but then there are other indications present. But the one above described he considers of great importance for early diagnosis of ascites. [W.K.]

4.—Knapp treats briefly of the advantages derived from the use of a jointed phantom in obstetrical instructions. Thus all the various positions before and during delivery may be clearly demonstrated to the student. [W.K.]

1. A Very Rare Form of Perineal Rupture. F. ENGLEMANN.
2. Vaginal Obliteration for Prolapse. S. STOCKER.
3. A "Gebärmantel." An New Apparatus for Increasing Abdominal Pressure During the Period of Expulsion. ALFRED JAKS.
4. A Very Simple Leg Support. KALABIN.

1.—Englemann reports a rare form of perineal rupture occurring in connection with the spontaneous delivery of a large child. The attendant said there must be an inner rupture since the child was born with a sudden jerk, and there was no external injury present. Examination showed a perineum 8 cm. in breadth, intact, except in the frenulum there was a small tear and near the anus an irregular opening communicating with the vagina, a kind of inner perineal laceration. Knowing that a central rupture may heal spontaneously, Englemann trusted that this would also, his only fear being that the fistula might become a passage for lochial secretions, but the fear proved groundless and in 14 days the fistula was completely closed. [W.K.]

2.—In 1896 two new procedures were shown as remedies for prolapse in elderly women. One by Freund relieved the prolapse in nonmenstruating women by drawing downward the uterus and stitching it to the vagina, the secretions being discharged through a new opening in the fundus. In the same year Wormser published a procedure by P. Muller in which the prolapse was remedied by excision of the vagina and the inclusion of the uterus and reported many cases thus treated with good results. Stocker fearing that hydrometra might develop in the uterus thus devoid of any external passage, devised a modification of the method, adapted to elderly women who still menstruated. He reports the case of a patient, aged 52, describes the operation, the first step of which was to make a long incision in the left side of the vaginal portio. The edges of this wound were stitched with catgut, uniting the mucous membrane with that of the cervical canal. Then a strip of the vaginal mucous membrane on the left side, about 5 cm. broad, was allowed to remain; all the rest was removed and the denuded surfaces united with sutures, thus leaving a very small passage for the discharge of all secretions. This operation was quickly and easily performed, and the results very satisfactory. [W.K.]

3.—Jaks, realizing that a proper position of the woman in labor is a great advantage in securing the necessary abdominal pressure at the period of expulsion, has contrived an

apparatus which serves the purpose of securing the best position. In an illustrated article he describes the apparatus, showing how by means of some strong material passing under the shoulders and hips and secured to the footboard of the bed by 2 sets of straps, support is given to the back, hips and shoulders, the symphysis is brought nearer to the chest, great contraction of the abdominal muscles secured, and the abdominal cavity lessened. The diagrams make clear its other advantages and the writer thinks it not improbable that by the help of this apparatus the forceps can be dispensed with in many cases in which they would otherwise be necessary. [W.K.]

4.—Kalabin describes a very simple leg support which he has used for 14 years and which serves as an assistant in many operations. It is of service especially in all perineal or vaginal operations, making it possible to do the work with one less assistant. The apparatus is simple and inexpensive. [W.K.]

November 24, 1900. [No. 47.]

1. Case of Chorioepithelial Vaginal Tumors. H. SCHMIT.

1.—It has been stated in numerous publications that after the conclusion of pregnancy, at the point of placental attachment, there are sometimes primarily developed chorioepithelioma, which are of a very malignant nature, and quickly lead to metastatic growths on the vaginal walls or in the lungs. Pick and Schmorr have added 2 new facts: First, that after molar pregnancy through migration of the vesicular fragments, a metastatic tumor may appear in the vagina; and second, that in other cases after pregnancy, multiple tumors appear in lungs, liver, and intestines, and cause death without their being any primary tumor of the uterus. Schmit gives a full description of a case of his own, and reports 2 others. 1. The case of Schmorr, in which there was a normal delivery at the end of pregnancy. The uterus was sound, but multiple chorioepithelioma in vagina, lungs, liver, kidney, and intestines caused the patient's death. 2. The case of Schlagenhauser was one of incomplete abortion. The uterus was sound, but there was an isolated vaginal tumor, from which the patient recovered. 3. Schmit's case was a molar pregnancy with spontaneous delivery. The uterus was sound and healthy, but there were 2 vaginal malignant syncytial tumors, the removal of which was followed by the patient's recovery. In both the last cases the tumor limited to the vagina could be determined early and operative help brought at the right time with resultant recovery. Now the question remains whether or not in both these cases a migration of fragments into the other organs had taken place. The probability is that it had not, since the inner organs remained healthy, but we must remember the possibility that such fragments might be carried through the blood to other organs and then pass away without doing any injury, as Schlagenhauser remarks, that not alone the anatomical, but also the individual disposition of the organism and its peculiar tissue must determine the existence or non-existence of metastasis. [W.K.]

1.—Kelling has carried out an elaborate research on the stomach, which is divided into two parts. The first deals with **gastroenterostomy** and the second with resection of the stomach and gastric ulcer. In his work on gastroenterostomy, his research consisted in experimentation on some 30 dogs. It was found that the pressure of the stomach during digestion in a dog was equal to a column of water from 3 to 10 cm. high. During vomiting this was increased $\frac{1}{2}$, sometimes $\frac{3}{4}$. On exciting the vagus nerve, the pressure reached 10 to 18 cm. The greatest danger for the suture lies in the possibility of introduction of solid bodies. According to Chlumsky, the sutures in this position may hold a pressure from 37 to 68 cm. Peritonitis lowers considerably the strength of the suture. It was found that gastroenterostomy in the fundus of the stomach allowed a more rapid emptying of the organ, and because of the frequent presence of large particles of food, there existed a tendency to dilation of the fistula. If there is an angular fixation between the pyloric portion of the stomach and the upper duodenum, the emptying of the stomach is greatly hindered, and in cases where this angular flexion exists, pyloroplasty should not be done. Gastroenterostomy performed with a button possesses many advantages over that of simple suturing; chief among these is the prevention of the formation of a ring of mucous membrane which projects into the stomach. Murphy's button presents disadvantages in that it acts as a large and heavy foreign body, and is therefore better to use some form of button which can be absorbed. [G.B.W.]

2.—Von Eiselsberg reports 6 cases of **stenosis of the pylorus** following the corrosive action of some chemical. In 2 cases hydrochloric acid was the chemical, in 1 sulfuric acid, in another nitric acid, and in 2 the substance was unknown. The patients appeared in from 4 to 12 weeks after the accident. The diagnosis was in all cases easy, and there was always typical symptoms of stenosis of the pylorus present. In 5 of the cases, the pylorus was alone injured, the esophagus remaining free. In 1 case both pylorus and esophagus showed the effects of the corrosion. For the relief of this condition, resection of the pylorus was done once, gastroenterostomy 4 times, and in 1 a second laparotomy was necessary. One case died from suppurative bronchitis, the rest were cured, 3 for 2 years, and 2 for a few months at least. The operation of choice in case of corrosive stricture of the pylorus, is gastroenterostomy. Resection is the simplest procedure, but in many cases it is contraindicated on account of the length of the stricture. Simple jejunostomy is seldom more than a palliative operation. [G.B.W.]

3.—Payr after a long research on animals and careful study of clinical cases, suggests the following method of **uniting severed bloodvessels**, which seems most practical and easily carried out. First, it is necessary to provide for temporary closure of the artery or vein. This is best done by means of a small spring forceps, the blades of which should be covered with rubber tubing. Supposing the artery to be severed transversely, if the artery be of small size, 3 fine silk sutures are passed through the whole thickness of the vessel-wall at the distal end. A small metal tube, slightly larger than the artery, is slipped over the threads and over the end of the bloodvessel; by means of the thread the artery is then turned cuff-like back over the tube, so that the intima faces outward. The tube possesses a groove so that by a circular ligature the bloodvessel may be securely fastened to it. The peripheral end is secured in a like manner by 3 sutures, and drawn over the distal end and fastened there by means of a circular ligature. This brings the intima of the distal and of the peripheral ends of the bloodvessel into direct relation with each other, so that a broad and firmer union may readily take place. The metal tube should consist of **metallic magnesium**. By a number of experiments it was found that magnesium when imbedded in the living tissue, is comparatively quickly absorbed. The disappearance of the metal is due to the formation of a soluble magnesium salt formed by the oxygen and carbonic dioxide, which are present in the tissue. Payr also presents another apparatus for closure of bloodvessel, resembling somewhat a Murphy button, and which has the

advantage of being somewhat more easily used than the above described method, but it does not give quite so satisfactory results. Also in suturing nerves, the use of magnesium tube presents many advantages, because of its being absorbed by the tissues. As to the rapidity with which the magnesium disappears when placed in living tissues it has been found that a piece of magnesium wire, 1 mm. in thickness, would in 15 days be broken into a number of pieces, and the thickness lessened $\frac{1}{3}$ to $\frac{1}{4}$ of its original diameter. [G.B.W.]

4.—Petersen reports 3 interesting cases of **malposition of the intestines following gastroenterostomy**. In all the cases the new position of the intestine was the same though different in degree. The condition consisted, first, in the twisting of the axis of the displaced intestinal loop to about 90°; and, second, that the displaced gut, which consisted of the efferent limb of the anastomosis, passed through a ring formed by the stomach, the afferent limb and the posterior abdominal wall. This displacement did not lead to direct strangulation of the intestine, or to a disappearance of the intestinal circulation. The important pathologic condition consisted in a twisting, bending, and bruising of the mesentery, which necessarily followed the gut through the opening. In the first place, the displacement was so slight that no positive clinical symptoms were manifest. In cases 2 and 3, so much intestine was drawn through the ring that extensive thrombosis of the mesenteric veins was caused, giving rise to hemorrhagic infarct, paralysis, and beginning necrosis of the intestine. In the second case, the thick and twisted mesentery so pressed upon the duodenum as to obstruct its lumen, and cause retention of the bile to such an extent that the distention following caused the suture to give way, perforation and peritonitis resulting. Peterson, after looking through the literature carefully, could find no case exactly corresponding to the above. He believes that the most important element in the production of this displacement of the intestines is to be found in the technic of the operation. This is especially true when use is made of the Murphy button. When simple suture is done, the intestine is fastened to the stomach, one lying parallel to the other, and the early stitches prevent displacement, but when one uses the Murphy button, the twisting and pushing which attends the operation places the intestinal loops in such a relation to each other as to predispose the condition above cited. He further says that sometimes the gauze tampons are so placed as to involve some intestinal loop, so that its withdrawal may bring the efferent loop through the ring above described. The lessons to be learned from his study are, first, that the field of operation should be sufficiently large to enable the operator to clearly see the position of the loops concerned in the anastomosis; and, secondly, that all openings caused by the operation should be closed as far as possible. [G.B.W.]

5.—Samter describes the following **operation for the treatment of habitual dislocation of the shoulder**. The first step consisted in establishing a free approach to the joint; the usual oblique incision on the anterior surface of the shoulder, between the pectoralis major and deltoid, does not suffice for this purpose, and should be supplemented by a transverse incision running from the upper end, the first incision horizontally outwards, and which is combined with loosening of the deltoid from the anterior angle of the clavicle. Second, the joint capsule should be opened in every case, as otherwise the opportunity for inspection of the joint itself, and the chance of the discovery of foreign bodies would be lost. Third, the capsule should be folded upon itself, as recommended by Mikulicz, and a suture placed through the lower edge of the incision in the capsule is carried through the coraco-acromial ligament and tied; also the tendon of the subscapular muscle should be fastened by a suture to the capsule. In cases where the bone is very much changed, the shortening of the capsule is often favorably combined with some slight osteoplastic operation on the ends of the bone. [G.B.W.]

6.—The case reported by Gottstein was remarkable in that the patient after **complete removal of the larynx** was finally able to speak, apparently without the use of the lungs and the ordinary sound-producing organs. The man was 47 years of age and had been suffering for 4 years from a gradually increasing hoarseness until lately dyspnea developed. Pain had never been present, even in swallowing or

coughing. The laryngeal examination and endolaryngeal removal of a portion of the tumor for diagnosis showed the growth, which involved the greater part of the larynx, to be carcinomatous. The operation was done under chloroform. Laryngotomy was performed and the growth was seen to be so extensive that total extirpation of the larynx only could be considered. After dissecting the larynx free from the surrounding muscles, the trachea was cut through just below the first cartilage, and the larynx turned upwards and removed just below the epiglottis. The tracheal stump was stitched into the lower part of the wound. The mucous membrane of the pharynx was closed by a layer of catgut, and the muscles united over it by another catgut suture. The greater part of the second wound was also united by sutures. The patient stood the operation well and was discharged from the hospital with a specially adapted talking apparatus. The apparatus consisted, first, in a piece which fitted into the tracheal opening; second, in a rubber tube stiffened by spiral wire; and, third, in a metal tube which reached into the mouth to the last molar tooth, and which possessed an oval opening on the side near the internal end, through which the air coming from the trachea found exit into the mouth. In the rubber tube two small apparatuses were placed. One was a valve which enabled the air during inspiration to enter directly into the tube, without first passing through the mouth, and the second was a vocal apparatus, by which an artificial sound was produced from the air passing through the rubber tube. With this apparatus the patient could talk loud and distinct, though in a somewhat monotonous voice. As this apparatus caused more or less annoyance to the patient, advantage was taken of the fact that the patient was able to produce certain sounds by the mouth alone, and after training and much exercise in vocal maneuvers, the patient returned one day to the hospital able to speak in a distinct and loud voice without any sort of artificial apparatus. After more practice, the patient was enabled to change the pitch of his voice to the extent of almost a whole octave. A study into the production of this voice, showed that the tone itself was produced by the muscles of the larynx contracting in the region of the epiglottis. The air, which set in vibration the tone-producing folds, was obtained from a space which had formed just below the epiglottis. This wind-chamber was filled and emptied by the muscles of the neck. It was also found that a second space had developed below the first air-chamber, and this reserve depot enabled the patient to utter a number of words one after another without drawing in new air. [G.B.W.]

7.—It is a known fact that in the region surrounding tuberculous disease of the bone, a marked **atrophy** or disappearance of the bone substance takes place, not only in the diseased bone itself but in the adjoining and otherwise healthy portion. This atrophy is diagnosed by the use of the x-rays, and Sudeck reports a number of cases of atrophy of the bone following inflammatory disease of the surrounding soft parts. In these cases the condition was very acute, developing within 6 or 8 weeks, but disappearing in time under proper treatment. This condition is not one of functional atrophy following a lack of use of the part, nor can it be ascribed to atrophic changes, as the result of reflex irritation through the spine. It is most probable that an inflammatory irritation exists to a much greater distance than the diseased area itself, and this irritation brings about certain disturbances in nutrition which lead to the atrophic changes. [G.B.W.]

8.—Hagen reports a most interesting case of **pancreatic cyst** occurring in a boy 13 years of age. Before the operation the diagnosis was possible only in so far that an inflammatory fluid was thought to be present either in the abdominal cavity or in one of the abdominal organs. Laparotomy was performed and after opening the abdomen, a cyst about the size of a child's head was found, posterior to the stomach, firmly surrounded by adhesions, so that it was impossible to bring the cyst wall in contact with the abdominal wall, and equally impossible to remove the cyst as a whole. The only hope of saving the child's life, however, was in the evacuation of the cyst. Approach to the cyst was finally gained by first incising the anterior gastric wall, and then through the cavity of the stomach the posterior gastric wall was reached and the cyst opened. The contents of the cyst were easily removed. A finger passed in through the openings found the least external resistance on the left

side of the cyst, and with difficulty the stomach was here displaced a little towards the right, so that pushing firmly on the abdominal wall the cyst could be brought in contact with the parietal peritoneum. The 2 wounds in the stomach were sutured, first that on the posterior wall, and afterwards that in the anterior wall. In order to allow the abdominal wall to fall in to a sufficient extent to come in contact with the cyst, it was found necessary to resect a part of the ninth and tenth rib cartilages. The cyst was then sutured to the abdominal wall, and opened. Examination of the cyst showed that it was evidently the result of a chronic interstitial inflammation of the pancreas. The patient stood the operation well, and 2 months afterwards the cyst had disappeared and the pancreatic fistula had closed, and the patient had gained 20 pounds in weight. [G.B.W.]

9.—Hagen proposes the following procedure for the closure of **ventral and umbilical hernia**. He based his operation on the idea of covering the defective and thin cicatrix by muscular flaps. After incision through the abdominal wall, the peritoneum and fascia are united by sutures. After extensive lateral loosening of the skin, the external sheath of the rectus is divided at about the middle of the belly of the muscle; carefully avoiding the nerve-branches, a portion of each muscle is loosened so that it may be turned inwards, placing the external portion of the muscle against the already sutured fasciae. These muscular flaps are sutured in place and the skin united over them. Hagen says that he has had great success in the practice of this operation. [G.B.W.]

10.—After an examination of 15 specimens of gangrene of the lower leg obtained by amputation, of which 5 were senile gangrene, 5 diabetic gangrene, and 5 spontaneous gangrene; Bunge comes to the following conclusions: In cases of arterial sclerosis, a high grade sclerotic proliferation of the intima was apt to be found, causing stenosis of the lumen of one or more of the chief vessels of the extremity. This condition was either diffuse, or occurred as multiple, more rarely single, circumscribed stenotic proliferations, sometimes causing a complete obliteration of the lumen of the vessel. This primary stenosis threatened the life of the extremity, first in that the exit of the branches from the vessel involved were closed by the process, thus preventing the establishment of collateral circulation and secondly in that a secondary progressive thrombosis was apt to develop on the changed arterial wall. In certain cases, especially those of senile or diabetic gangrene, a circumscribed petrification of the arteries sometimes forms, and which has the same clinical importance for the circulation, as the already stated conditions. In these cases of gangrene, the only treatment is amputation, though often it is not necessary to go above the knee for the point of selection. [G.B.W.]

11.—Lately the operation of **splenectomy** has been growing rapidly in favor, and as the operative technic improves, the mortality percent has greatly lessened. It has been shown by experiments on animals and by observations on persons, that it is entirely possible to remove the spleen from an otherwise healthy man, without having any serious symptoms develop. Hagen has quoted 360 cases of extirpation of the spleen, 138 of which were followed by death. In another series of cases quoted, 97 operations before the year 1890 showed a mortality of 42.02%, and 164 between 1891 and 1900 showed a mortality of only 18.9%. Total extirpation of the spleen should never be done for leukemic hypertrophy, as statistics show a mortality of 71.4%. In cases of traumatic rupture of the spleen, extirpation offers the best chance of saving the patient's life. Splenectomy gives even more favorable results in cases of splenic abscess. In tuberculosis, the spleen should be removed when the organ is surrounded by an accumulation of pus, and is not fastened by any particular adhesions to the surrounding structures; in other words, when there is no danger of causing a general infection of the abdominal cavity. Echinococcus cysts occurring in the spleen generally demand removal of the whole organ. Also in cases of neoplasm, complete splenectomy should be performed. In cases of floating spleen, splenectomy should be given the preference over splenopexy. Of late years, the operation in cases of malarial hypertrophy has shown a great decrease in the mortality, and even affords brilliant results, not only in relieving the patient of a large tumor, but in bettering his general condition. In primary hypertrophy of the spleen, associated with interstitial hepa-

titis, the operation of splenectomy should be performed as soon as possible before serious change has been able to develop in the more important organ. For similar reasons, a spleen which shows simple idiopathic hypertrophy, should be removed in order to protect the liver from severe and incurable disease. Hagen reports a case of primary hyperplasia of the spleen, associated with interstitial hepatitis, occurring in a woman of 26. The case was greatly benefited by the removal of the spleen, and from month to month she continued to show progressive improvement in her general condition. Furthermore, Hagen reports 2 cases of metastatic inflammation of the spleen, one following a gangrenous chancre, and the other a epityphilitic abscess. In the first case there was suppuration and necrosis of almost the whole of the spleen, and the case recovered perfectly after splenectomy. In the other case there was multiple abscess following the appendicitis with marked symptoms of sepsis. Splenectomy with partial extirpation of the spleen, after resection of the ninth and tenth ribs, was done, and the case recovered. [G.B.W.]

12.—Wolff says, regarding the indications for operation in **carcinoma of the rectum**, that much depends upon the individual merit of the surgeon, and upon the peculiarities of the case. Bergmann operates in even those cases in which there are numerous adhesions to the surrounding structures, and practically refuses operation only where old age and general condition forbid any surgical procedure. Where the tumor occupies a high position, and where there is much glandular involvement, the operation required is most extensive and difficult. The best methods of operating in all cases, except in those where the carcinomatous process is limited to the lower part of the rectum, is through a dorsal incision. Just how far the new abdominosacral method, suggested by König and others, offers more advantages, still remains to be seen. The temporary resection of the sacrum and coccyx, as suggested by Schlange, opens a wide path to the seat of the disease, but presents the disadvantages of severe hemorrhages, and of leaving a large wound to heal. [G.B.W.]

II Policlinico.

(Sezione Pratica.)

November 17, 1900. [Anno vii, Fasc. 3.]

1. On Exomphalos. S. FERRANTI.
2. Transactions of Congresses.
3. On the Best-known Colorimetric Methods for the Quantitative Determination of Nitric Acid in Water. V. BARONE.

1.—Ferranti relates a case in an infant in whom **umbilical hernia** developed 30 hours after birth. The tumor attained to a large size, yet was reduced in the course of a few days by the simple application of a bandage. He discusses the theories of the production of umbilical hernias and the distinctions between them and diverticular hernias and urinary omphaloceles. The various methods of treatment he resolves into two, the first consisting in the reduction of the hernia and the closure of the ring or sac by sutures (annulorrhaphy), the other in the removal of the umbilical ring and suture of the parietes, as in a laparotomy (omphalectomy). The indications for and against surgical intervention are stated and treatment by bandaging recommended in suitable cases. A bibliography is appended. [G.S.B.]

2.—At the congress of the Italian Surgical Society, Fummi opened a discussion on **medullary anesthesia** with a report of 40 cases operated upon in Montenovise's wards at Santo Spirito. Encouraged by experiments on dogs he used a solution of cocain in glycerin for injection and obtained anesthesia in the thorax, neck, and upper limbs as well as in the lower part of the body. Owing to the high specific gravity of the solution in glycerin it is enabled to ascend through the cerebrospinal fluid as high as the cerebral ventricles. Bastianelli and Fioretti related their experience of the method from a total of 35 and 25 cases respectively. The former surgeon laid stress upon the need of a full muscular relaxation as one of the contraindications to its employment. Damascelli read a "Contribution to the His-

tology of some Tumors of the Jaw," tracing their origin to the paradental epithelial residence found in the adult jaw which are germs of the embryonal dental membrane. Catterina showed a periosteal angiosarcoma removed from the palate, and a carcinoma of the parotid, the origin of both of which he ascribed to embryonal germs. Maffucci described the symptoms and postmortem appearances in a case of primary malignant lymphoma of the stomach, remarking on the rarity of such growths and the fact that many of them are undoubtedly of infective origin. Dalla Vedova related the results of experiments on dogs from which he concluded that by injury to the extrinsic sympathetic innervations of the stomach (celiac plexus, splanchnics) ulcers strictly analogous to those in the human subject might be produced. At the Obstetric and Gynecologic Congress Marocco read a paper on hysteropexy without suture, and Ferrari and Caturani contributions on the surgical treatment of posterior displacements of the uterus, for which the latter proposed a new operative procedure by vaginal fixation of the round ligaments. Vicarelli advocated the tamponage of the uterus in cesarean section (Sänger's operation) as a means of preventing subsequent hemorrhage and infection. Truxxi suggested some changes in the technic of the unilateral operation for removal of the uterine adnexa. D'Alessandro described a new instrument for the permanent and bloodless dilation of the external or internal os uteri. Amadei and Ferri presented the statistics of placenta prævia in the *Guardia Ostetrica*, of Milan, from January 1, 1897, to September 30, 1900. Out of a total of 5,136 cases there were 97 of placenta prævia (1.89%), central in 28, and marginal in 69 cases, with a maternal mortality of 5 cases, and a fetal mortality of 41 cases out of the 80 cases in which the fetus was viable. Turning was employed in 42 cases, the forceps in 7 (all marginal), and embryotomy in 3 cases. [G.S.B.]

3.—While the method of Schulze and Thiemann is admittedly the most accurate for the **quantitative determination of nitric acid** in water, its difficulties of execution have led chemists to employ by preference various calorimetric methods as being shorter and more simple. Of these Barone prefers the reaction with diphenylamin of Hoffmann, which is in general use as a qualitative test for nitrates in water, and he has attempted to utilize it for quantitative purposes by comparing the tint produced in the sample of water with that formed by the action of diphenylamin and sulfuric acid upon different dilutions of known strength of specially prepared nitric acid. The sources of error are, however, so numerous that even then the colorimetric method is not to be recommended as an exact one. [G.S.B.]

A Case of Atrophic Cirrhosis of the Liver with Preascitic Edema.—Morano (*Gazz. degli ospedali e delle clin.*, 1900, No. 117) attributes the preascitic edema in atrophic cirrhosis of the liver to circulatory disturbances in the vascular tone of the vena cava, resulting from the hepatic inflammation. The vena cava can also have its lumen decreased by the sclerosis in the liver lobules in which the vessel is imbedded. The resulting edema varies in intensity according to the rapidity with which the collateral circulation is established. [M.R.D.]

Akromegaly.—Bregman (*Deutsche Zeitsch. f. Nervenheilkunde*) reports a case occurring in a man 41 years of age. In childhood both thumbs were exceptionally large and thick, apparently a family peculiarity. The disease commenced about the age of 38, the earliest symptoms being weakness, especially on the left side of the body, and excessive thirst; the symptoms were in general quite typical; the skin was greatly thickened on the hands, and there was considerable desquamation, and falling out of the hair on the left side of the body; in addition there was glycosuria, and extreme atrophy of the left half of the tongue; the whole left side was slightly paretic; there was no indication of the presence of a brain tumor, in particular no disturbance of the eyesight, excepting that due to a moderate glycosuric retinitis. The cause of the condition is probably some congenital defect; it is possible that the severe labor to which he was subjected, contributed in some way. [J.S.]

A CASE OF URETHRORECTAL FISTULA CURED
AFTER A THIRD OPERATION.

By ORVILLE HORWITZ, B.S., M.D.,

[of Philadelphia, Pa.]

Clinical Professor of Genitourinary Diseases, Jefferson Medical College;
Surgeon to the Jefferson, Philadelphia, and Children's (Germantown)
Hospitals and Hayer Mechanics Home.

URETHRORECTAL fistulæ are the most infrequent of any of the maladies connected with the urethra. All authorities agree upon the extreme difficulty of curing this disorder. I am in accord with Simon Duplay when he says: "There are some examples of spontaneous recovery of urethrorectal fistula; it must be acknowledged that most frequently they last indefinitely and the chances of cure by surgical interference are extremely few."

The literature on the subject throws but little light on the matter and leaves the student in doubt as to the best method to be pursued in order to obtain a cure. Surgical authorities differ widely as to the most suitable operation to be performed, each having its advocates as well as its detractors, and I have thought that by giving a brief account of the difficulties and failures encountered whilst attempting to remedy a case of urethrorectal fistula which came under my care, it might not only be of interest to the profession, but serve as a guide to other operators in search of the best method to be pursued when dealing with cases of this nature.

Urethrorectal fistulæ are, in their origin, either traumatic or pathological. Fistulæ may result from the lodgment of foreign bodies in the rectum or urethra; they have occurred after perirectal lithotomy, and from wounds and abscesses in the prostate gland, especially if the latter condition be due to tubercle. Pressure from stone in the prostate gland or the impaction of a calculus in the posterior urethra has been known to cause them. Cancer of the prostate, or abscess of the rectum, the latter usually associated with an hemorrhoidal condition, has given rise to fistula. In two instances, whilst performing the operation of prostatectomy by means of a perineal incision, I have been so unfortunate as to wound the rectum, resulting in a urethrorectal fistula in each case; they both, however, fortunately healed spontaneously.

So far as I can discover the cause in the case I am about to recount is unexampled. An attack of acute posterior urethritis gave rise to an abscess which was connected with the membranous urethra, finally rupturing into the rectum, and forming a fistulous connection between the two canals.

The patient was brought to me by Dr. Henry Heilerman, with the following history: He was 22 years old, by occupation a car conductor; he had contracted his first attack of gonorrhea during the month of October, 1898. At first there was profuse discharge from the urethra, with little pain; the discharge then became very slight, with a frequent desire to micturate, followed by the voidance of blood at the termination of each act; this condition was associated with pain in the perineum together with spasm at the neck of the bladder, and difficulty of urination. The temperature rose to 103°. He complained of constant pain in the rectum, with tenesmus, and a continual desire

for defecation, which, being associated with irritability and spasm at the neck of the bladder, caused the agony to be unendurable.

A digital examination of the rectum disclosed a fluctuating swelling of considerable size, very tender to the touch, presumed to be an abscess of the prostate gland; 24 hours later there was a sudden discharge of pus and blood from the bowel, followed by instant subsidence of pain, together with fall of temperature. After this the greater portion of the urine was passed per rectum instead of by the urethra.

When admitted to the Jefferson Hospital the patient was in very poor physical condition. He was pale, anemic, had lost weight, passed his urine every hour and suffered constant pain both in the rectum and at the neck of the bladder. The two-glass urine test showed both to be cloudy, containing pus, epithelium and a trace of albumin. The bladder could not contain more than one ounce of urine at any one time. When this amount had accumulated the fluid would begin to dribble, and to flow over the buttock and thigh, which were in consequence continually moist and

FIG. 1.—Showing the fistulous connection between the rectum and urethra.

excoriated; in spite of every effort to keep the patient clean a most disagreeable odor was constantly present.

After a rest in bed of 10 days, with the necessary preparatory treatment, the condition of the patient had so much improved that it was considered safe to make a urethral and rectal examination. A 24 F. bougie was passed into the urethra, and the patient placed in the "knee-chest" posture; on inserting a bivalve rectal speculum a fistulous opening could be seen on the roof of the rectum, about 1½ inches from the sphincter muscle, apparently at the junction of the membranous and prostatic urethra. A filiform bougie was readily inserted along the fistulous tract from the rectum into the urethra. The fistula was found to run upward and backward and enter the membranous portion of the canal. An endoscopic examination of the urethra showed that the opening of the fistula into the urethra was smaller than that at the rectal orifice. This, together with the fact that the course of the fistula was upward and backward, accounted for the flowing of the urine so readily into the rectum, and at the same time rendering the passage of fecal matter from the rectum into

the urethra or bladder impossible. Occasionally flatus could be passed by the urethra.

On consulting the various authorities in order to determine upon the most satisfactory operation to be elected whereby to effect a cure, I found that the many articles that have been written on the subject are in the main quite unsatisfactory.

Owing to the size of the rectal orifice of the fistula, together with the position and length of the sinus, I decided against the employment of either chemical caustics or electro- or thermocautery. Not only do all authors agree that they more frequently fail than succeed, but that this method of treatment is only suitable to the very narrow fistula. The various plastic operations suggested by Sir Astley, Cooper, Desault, Duplay, Brown, and others did not appeal to me, and I decided to try an entirely different expedient than any hitherto suggested.

FIG. 2.—Showing filiform inserted in the fistulous opening in the rectum passing through the urethra into the bladder.

The patient was prepared for operation in the usual manner, etherized, and placed in the lithotomy position with the buttocks well elevated above the operating table. A 24 steel bougie was passed into the urethra. A horse-shoe incision was made, beginning midway between the tuberosity of the ischium and the sphincter ani at the right side across the middle of the perineum, then downwards to a corresponding point on the opposite side from which it started. The rectum was then dissected free from the surrounding tissue until the fistulous communication between the rectum and urethra had been separated. The fistulous opening in the bowel was freshened, and after a great deal of trouble the opening was closed by means of 6 silk sutures. An incision was then made in the median line of the perineum, opening the membranous urethra just as is done when performing the external perineal urethrotomy by means of a guide. This was done

with a view to freshening the edges of the fistulous opening in the urethra. The bougie was now removed and a soft rubber catheter inserted and allowed to remain in situ, thereby establishing continuous drainage. The perineal wound was packed with iodoform gauze so as to shut off all communication between the rectum and urethra. An effort was made to keep the bowels confined for one week after the operation; unfortunately on the fifth day the desire for defecation became imperative. During the bowel movement the catheter was expelled from the urethra. Unfortunately my trained clinic nurse was absent on his summer vacation and the individual on duty had had but little experience in urethral surgery, and in his efforts to insert the catheter, reopened the wound in the bowel so as to again establish the fistulous communication. For some time after this the patient suffered from a urethro-perino-rectal fistula, both urine and feces discharging from the perineal wound as well as from the rectum. Gradually the wound in the perineum closed, leaving the patient in the same condition as before the operation except that the rectal orifice of the fistula was much smaller and nearer to the external sphincter. Dr. Keen, who saw the case at this time in consultation, advised that the actual cautery be tried. Acting upon this suggestion, the patient was again placed under the influence of an anesthetic, and a preliminary suprapubic cystotomy performed in order to deflect the urine from the urethra and thus give the fistulous tract a better chance to heal. The rectum was exposed by means of a Sims speculum; the fistulous opening thoroughly seared by means of the thermocautery. The bladder was drained by means of the suprapubic opening for the space of about 3 weeks, by which time it appeared as if the communication which existed between the urethra and rectum had become obliterated. The suprapubic wound was allowed to close and for about 10 days no urine passed from the urethra into the rectum and the case was looked upon as cured. Suddenly, however, a small abscess appeared at the site of the old opening in the rectum, which, on rupturing, reestablished the old fistulous tract. The patient was sent home for a couple of months in order to recuperate before attempting another operation for his relief. On his return to the institution a third operation was performed, which proved successful.

On examination, the general condition was found to be about the same as before the second operation was undertaken. Then it was decided to attempt to close the fistula the third time by employing a method similar to that pursued when repairing vesicovaginal fistula, and known as the "American method;" that is, by denuding the margin of the opening and approximating its edges by suture. In order to place the patient in proper condition for the operation he was kept in bed for a week, he was placed on light diet, the bowels being kept freely open by means of laxatives. Continuous drainage was instituted so that the parts might become accustomed to this condition, as it was proposed to make use of this method so as to keep the wound free from the urinary discharge after the operation. At the end of 10 days the patient was placed in the lithotomy position, the sphincter ani well dilated, and the Sims speculum inserted. The anterior wall of the rectum was drawn down by means of the hemostatic forceps, the edges of the fistulous opening, as well as the mucous membrane within a quarter of an inch surrounding the orifice, were denuded. This procedure

was found difficult to accomplish, as the operation was necessarily frequently interrupted in order to control hemorrhage which obstructed the view of the field of operation. The denudation was finally completed and the opening closed by means of 5 silkworm-gut sutures, starting on the mucous membrane, a little beyond the denuded margin on one side, and passing out at a corresponding point on the other. Inserting the sutures was the most difficult part of the operation; the threads were allowed to remain about 4 inches in length, and to protrude outside the sphincter muscle. This was rendered necessary that they might be easily reached when it was desired to remove them. The bowel was irrigated with a saline solution and "Pennington's hollow rectal tampon" inserted. The tampon served not only to prevent spasm of the sphincter muscle, keeping the parts at rest, but served at the same time to protect the wound, and, what was most important, provided for rectal drainage. Had a movement of the bowel become necessary it could have taken place without pain, and the wound would have been protected from the danger of infection. By means of the deodorized tincture of opium the bowels were rendered quiescent for 7 days after the operation, when they were moved by means of repeated doses of sulphate of magnesia and a large enema of hot water. The tampon served to drain a large quantity of serum, some liquid feces, and to permit the escape of flatus during

the time it was in place. The stitches were removed on the eighth day after the operation, when it was found that firm fibrous union had taken place. The urine was disposed of by means of continuous drainage for 2 weeks after the sutures were removed. The patient was discharged cured, and has remained in perfect health ever since.

In studying the history of this case there are two points pertaining to it that attract attention. The first is the fact that as soon as the gonorrheal infection spread to the urethra the temperature rose to 103°, showing that almost at the start there must have been a periurethral inflammation with a tendency to the formation of abscess, as it is well known that in uncomplicated cases of acute posterior urethritis there are no constitutional symptoms. The second is that although the patient had a healthy rectum and sphincter ani, yet as soon as urine to the amount more or less of one ounce accumulated in the rectum, dribbling took place, keeping the parts constantly wet. This would seem to indicate that in cases of malignant disease, or of extrophy of the bladder, where resection becomes necessary, with implantation of the ureters into some portion of the intestinal canal, that it would be wiser to have recourse to the sigmoid flexure, instead of to the rectum.

My experience gleaned from this case would seem to lead to the conclusion that when dealing with a similar condition of affairs, it would be proper to keep the patient on a light diet for at least 10 days previous to the opera-

tion; the bowels to be frequently freely moved, so that they may be controlled after the surgical procedure at the same time a continuous drainage to be instituted so that the individual may be accustomed to the method of drawing off the urine, and the urethra become tolerant of the presence of the catheter. If the rectal orifice be large, and situated some distance from the sphincter ani, the operation that was resorted to primarily is considered preferable, and is recommended. It would have doubtless succeeded in this instance but for the bungling of an incompetent nurse. If the opening in the rectum be situated in the vicinity of the sphincter the plastic operation, which was here so successful, is to be preferred.

FALLACIES CONCERNING THE MENOPAUSE.

By GEO. ERETY SHOEMAKER, M.D.,

of Philadelphia.

Copyrighted by the Presbyterian and Methodist Hospitals.

In the year 1779—121 years ago—John Fothergill, M.D., F.R.S., in writing a paper for the Medical Society in London, used these words: "The various and absurd opinions relative to the ceasing of the menstrual discharge, and its consequences, propagated through successive ages, have tended to embitter the hours of many a sensible woman. . . . Some practitioners, other respects able and judicious, if they have not favored these erroneous and terrifying notions, seem not to have endeavored to correct them with the diligence and humanity which an object like this requires."¹

The terrifying opinions referred to by John Fothergill were such as this: That the normal menstrual flow was an evacuation of morbid material or "humor," and that its failure to escape from the body by reason of the onset of the menopause, must be injurious, as noxious material was retained. Again, it was thought that the flow at this time had a special defiling or injurious magical influence on persons or objects.

Such views have long been abandoned by the medical profession, though large numbers of women still think that some serious disorder is liable to set in at that time of life. It would seem, in fact, that medical opinion has swung entirely too far in the opposite direction, so that at the present day, any disorder occurring near the menopause, so far from exciting the slightest apprehension on the part of physicians or patients, is apt to be entirely neglected, as though it were all in the disordered course of Nature. The consideration of fallacies regarding the menopause, prevalent at the present day, must deal, therefore, not with the terrors of the condition, but with an almost fatalistic neglect of real disease.

In large numbers of instances, where women over 50 years of age apply to the gynecologist with any sort of pelvic disease accompanied by hemorrhage, they will state that they have for a long time attributed the symptoms to the change of life and were finally driven to seek relief by the increase of the trouble. Too often they state that their physician, without making any investigation, has assigned the same origin to the symptoms. Indeed, for a period of 25 years in a woman's life, i. e., from 35 to 60 years of age, it would seem that "the change of life" is popularly supposed to cover every pelvic or abdominal symptom. To this state of affairs, rather than to any other one cause,

due the prevalent large fatality from cancer. Cases are not investigated soon enough to allow of real help. A few months ago a woman was sent for an opinion by her physician. She complained of constant severe bleeding and was about 45 years old. Asked whether she had had the change of life she replied: "Oh, I am going through that now." She had a large fungating epithelioma of the cervix, but absolutely refused operation. The first and greatest fallacy therefore is, that persistent and severe symptoms of any kind, aside from obviously nervous flashes of heat and the like, attend the normal menopause. The menopause is not a disease, nor is it attended by disease. It is simply a period of readjustment extending over a term of one, two, or three years usually, and accompanied by vasomotor disturbances and a few functional nerve-symptoms.

The view is most dangerous that uterine hemorrhage, persistent and severe, is a symptom of the menopause, and that it may be neglected on the theory that time will cure it.

The total loss of blood in a given series of months is never excessive under normal conditions. If no flow is seen for 2, 3, or 5 months, and then a single free bleeding occurs, even if the quantity is great at this one time, there is nothing necessarily abnormal. By questioning it will be learned that the total quantity divided by the total number of missed months would not be excessive for each month. There is, on the contrary, no justification for considering a flow physiological, when it recurs nearly every day, or every week, or every 2 weeks, for months, or years; nor when by comparing a number of months, say 6, it is found to be steadily increasing; nor when the total quantity amounts to 4 or 5 napkins a day for prolonged periods, and when these periods occur too often in the year. Yet this error is constantly made.

Dr. John Milton Duff questioned 482 healthy women over 52 years of age in regard to bleeding during the menopause, and found that out of this number only 39, or 8.2%, had any history of what might be called hemorrhage.²

Owing to the prevalent idea among women that hemorrhage is to be expected, they allow excessive flowing to go on for a very long time without consulting a physician. When they do finally become alarmed or suspicious, they commonly spend some months in overcoming a modest hesitancy in speaking about it. When at last they do this, it is apt to be in a casual way, and with a ready-made diagnosis that it is the "change of life coming on." This they do with the hope that the physician will agree with them, and that no examination need be made. The physician may avoid a blunder which will afterward cost him much in reputation, and his patient much in welfare, if he will at once proceed to find out definitely whether or not she is bleeding too much by methodical questions along the following lines:

a. What was the normal for that patient in early life—that is, how many days' flow? At what interval? Did she use more or less than 3 or 4 napkins per day?

b. Establish the approximate time when she left her normal, and the average flow increased. This will often lead back several years, to a miscarriage, or a pelvic inflammatory attack, and will at once increase the probability that the excessive flow antedated the menopause and has no relation to it.

c. Show that the loss of blood is or is not progres-

sively increasing, taking months or years together. If it is steadily increasing, the periods becoming longer and nearer together, a local condition involving at least the endometrium is almost certain, provided of course that the total quantities are pathological.

d. Put down in figures the dates of all recent periods for a year or more as far as the patient can remember; beginning thus: How many times were you ill last month? How long each time? *How many napkins?* How many times the month before? etc., etc. This will often bring out a history of very serious hemorrhage, into the details of which the patient would not otherwise enter, but simply say she "loses too much." It will often be found that the patient has bled almost daily for many months. That she cannot measure the quantities by napkins, but goes to bed and uses a folded sheet, that she hurries to the water closet and passes large vaginal clots followed by a gush of blood, or, as one patient expressively said a few days ago, she "could use a bucket." It may show that she has not actually missed any periods, or, worst prognosis of all, that the cessation definitely occurred and that in a year or more flowing began again. Malignant adenoma or other form of malignant disease is then almost invariably present. Such a definite investigation patiently made will usually indicate whether an examination is called for. The physician will remember that a normal period lasts 4 or 5 days. The napkins may number daily from 2 to 5 moderately wet. The interval should not be less than 3 weeks, and that any marked deviation, to be normal or physiological for that person, must extend back into the period of young womanhood.

If an examination is indicated let it be made at once, and thoroughly, as a normal cervix does not exclude cancer. Three times during the past year I have operated by vaginal hysterectomy in cases of well-marked carcinoma of the fundus uteri where the cervix appeared absolutely free from the disease, and where a superficial examination which depended only on what could be seen through a speculum would have failed to detect the cancer. Nothing can be more dangerous to the patient than deferring examination until all the classical symptoms of cancer are present, namely: odor, pain, flocculent watery discharge in addition to bleeding. By the time these have appeared operation is often useless as far as freedom from recurrence is concerned. Examine all cases which have unnatural bleeding, and do not wait.

Another fallacy is that with fibroid tumors of the uterus which are growing or causing disturbance, the patient will do well to wait for the menopause. This idea arose when the mortality after fibroid hysterectomy was over 50%. Now, when it is 6% or less, in cases without heart and kidney lesions or pus tubes, and when hemorrhage has not brought the patient to the verge of the grave, the question of operative treatment stands on a different basis. The hope that the menopause will cure the case is in itself fallacious. These patients bleed till they are 55 or more years of age, thus waiting 20 years for the menopause if they begin to wait at 35, as some do. Meanwhile they are subject to peritonitic attacks, to tube degenerations (and few fibroids are accompanied by normal tubes), and to pressure effects on iliac veins, kidney, bladder, bowel. Their heart-muscles degenerate, while anemia directly invalids them besides aggravating all intercurrent disease. Many die while waiting for the menopause. Should some survive till after a long belated

² *Amer. Jour. Obstetrics*, November, 1899.

change has stopped the bleeding, the tumor diminishes but little usually, while the secondary lesions remain. There is no regaining of robust health. The 10, 15, or 20 years of invalidism while waiting do not bring a reward of returned youth and strength.

Let it be understood that it is not claimed that small fibroids require removal when they neither grow nor bleed nor cause symptoms. It is claimed that when these symptoms are present, waiting for the menopause to cure them is usually a losing game, because the menopause is deferred and all that makes life worth living is taken away by complications in the meantime.

The moral is operate early by removal, for fibroma of the uterus which is growing, which bleeds badly, or which by complication threatens the health of the individual.

It may be partly a coincidence, but the writer fails at this time to recall a case of uterine fibroid which gave trouble during menstrual life and which was cured after the menopause; where, in other words, it paid to wait. The cases not operated upon which did well after long waiting have been small, uncomplicated tumors which did not grow or bleed. Cases which found themselves rapidly going down hill and which dared wait no longer even though more than 45 years of age, have been numerous. These briefly illustrate:

Mrs. K, aged 52, widow, Ipara. Menstruation normal till aged 41, 9 years ago. Gradually increased in quantity since, till now almost constant bleeding. Very severe hemorrhage at periods, putting her to bed from weakness at that time. Losing flesh decidedly. Unable to work on account of weakness from bleeding. Formerly a strong, industrious hard-working woman. Right foot and leg swell. Bleeding steadily worse in spite of her physician's treatment. Operation, hysterectomy for adherent fibroma extending above umbilicus. Cured.

Mrs. T, aged 52, married, Ipara. Menses scant till age of 50, then severe bleeding began. Now pale, cachectic from anemia. Hemoglobin 39%. Has lost greatly in health and weight. Mucous stools for a year, alternating with constipation. Urination frequent and painful for a year. Both legs and feet swollen badly for a year. Very short of breath on walking. No heart-murmurs. *Diagnosis:* Multiple fibromata of uterus. After getting hemoglobin up to 47%, vaginal hysterectomy by morcellation. Cured. Nine months later shortness of breath had disappeared and nearly all edema of feet, by improvement in blood. Note that this patient's bleeding began after she was 50.

Mrs. D, aged 48, has a tumor reaching above the umbilicus, which has bled till her strength is gone. Her hemoglobin is 45%. She comes for treatment during her first attack of peritonitis. Temperature 102°, pain, tympany, etc. She has bled every day for two months. Her tumor is adherent, her general appearance poor. The feet swell and there is pressure pain in the lower extremities. What but hysterectomy offers her anything? How much more it would have offered her before the anemia was extreme and before this attack of peritonitis? She is now in the Presbyterian Hospital taking mammary extract and getting ready for operation.

H., aged 48. Widow, 7 children. Strong and vigorous till one year ago when hemorrhage from fibroma began. Gradually increased till dangerous. Only a few days between periods. Severe attack of catarrhal pneumonia never fully recovered from; still coughs. Steadily increasing weakness and hemorrhage. Hysterectomy; catarrhal pneumonia again set in. Death. Her trouble began at 47, and in one year had brought her into a desperate position.

S, aged 56. One child, 7 miscarriages. Fibroma for an unknown number of years. Menopause delayed until aged 54. One year later hemorrhage began again and rapidly became severe. Shown on operation to be due to adenocarcinoma of fundus, complicating the fibroma.

The number of cases like the last which appear in the experience of most men raises the question whether the

irritation produced by the fibroma is a contributing cause of the later development of the cancer.

It is unnecessary to multiply examples where the most serious conditions have menaced the life of the patient who has a fibroma after the time of the expected menopause. Yet patients, often under advice, continue to look in vain for its help.

WOUND OF THE TRACHEA. WITH SUTURE AND UNION BY FIRST INTENTION.

By E. S. GOODHUE, M.D.,

of Honolulu, H.I.

WOUNDS of the neck in which the trachea is involved are by no means infrequent. Usually they are self-inflicted by some insane or frenzied hand, unguided by knowledge or consideration of the relation of the tissues concerned. Hence, the head is thrown back, bringing the larynx into prominence, and leaving the important vessels of the neck out of reach of a carelessly-used instrument.

In exceptional cases the tissues of the neck are completely severed—carotids, trachea, esophagus, to the vertebrae—but, as a rule, the wound is superficial, owing to the extension of the neck, cartilaginous resistance, collapse of the thorax, or want of determination on the part of the would-be suicide.

In the case of a barber, aged 57, that came under my notice, the wound was made with a sharp razor, beginning at the right ear, and passing over the suprahyoid space to the extreme left—from "ear to ear," through all the tissues of the neck, including esophagus, and causing almost instant death. The question arose as to whether such a thing could be self-inflicted, but here was the case with absolute proof of suicide.

Generally, danger from hemorrhage is not so great when the larynx or trachea are much injured, as the large vessels lie outside of the path of such a wound; but cases are reported where the cut, beginning well under the ear, passed directly over the cricothyroid space. However, wounds of the larynx may be rendered serious by spasm and edema of the glottis, inflammation, or the passage of food into the trachea.

Hemorrhage occurs freely when the soft parts lying above the hyoid bone are severed. Often there is penetration into the cavity of the mouth, allowing the tongue or epiglottis, or both, to fall over the air-passage, thus causing death; or the lingual and facial arteries are cut, flooding the trachea. But greater hemorrhage is likely to occur when the carotid or thyroid arteries, the anterior, external or internal jugular veins, or the thyroid gland, are wounded in the lower part of the neck. Here, some of these vessels are generally involved, and if the trachea is completely severed, there is great danger that the freely-flowing blood will find its way into the lungs. This condition is made more serious by the fact that the trachea, upon being cut, retracts, the ends remaining difficult to approximate, while each inspiration and expiration renders the operation still more trying. These well-known facts are supported by the following case:

At 8 A.M., Sunday, July 25, I was summoned by telephone to Waikapu, a small village two miles from Makalani Hospital where I was. In less than half an hour, I reached the spot with my assistant, Dr. Wilbur McConkey, and found there Deputy Sheriff Scott, and a native policeman, waiting for us.

Lying on her back, near the house, was a Japanese woman with her throat cut, and life extinct. Nearby was the body of a little girl of four years, her head attached to the trunk only by a narrow strip of skin in the back, while, between the two, was the murderer, Sagata, a Japanese laborer, aged 39, with an ugly cut just below the cricoid cartilage, blanched, pulseless at the wrist, but still breathing.

When the officers arrived on the spot half an hour previously, Sagata lay on his face in a pool of blood with a dagger in his throat. He was then unconscious, as he was when I arrived. We at once placed the patient on his back, while I proceeded to examine the wound, at the same time requesting my assistant to give him a hypodermic injection of aqua ammoniae fort. 20 minims, in little over a dram of water.

I found a jagged cut half an inch wide, and about one and one half inches long, just below the cricoid cartilage, the opening being stretched by the knife, upon which the patient had lain.

The vessels were not bleeding much by this time, and there was no fresh hemorrhage when I removed the clots of blood and probed the wound. The superficial tissues were all cut through, and blood still oozed from the thyroid gland. The trachea, between the second and third cartilages, was completely severed, one inch or more existing between the retracted portions.

I was surprised to find very little blood about the inner edges of the trachea, but with each expiration, mucus from the trachea, and blood from the external parts, were blown out with a whistling, puffing sound. About five minutes from the time the first injection of ammonia was given, the dose was repeated, when the patient slowly opened his eyes. I quickly cleansed the wound with aseptic sponges and forceps, twisted the ends of the few vessels that still bled slightly, then attempted to bring the separated ends of the trachea together. This was not so easily done, although I finally succeeded in making a continuous suture with chromicised catgut. I included the inner and outer covering of the tube, in this continuous stitch, then to make provision against the tendency to reaction, I tied the cartilages together with three stitches, so that the approximated edges might be held as closely together as possible. I was much hindered by the smallness of the opening of the wound, which, however, I enlarged somewhat, making it nearly two inches wide.

Sagata now opened his eyes, looked around in a bewildered way, and asked for a drink of water, which we gave him with some brandy.

I now closed the external wound upon a small drainage tube, making the stitches with silk, covered this with aseptic dressings, absorbent cotton, and bandages, when the patient was taken to the hospital. Here he was placed in a ward prepared for him, and given special day and night nurses and attendants. After careful dressing of the wound by the nurse, the patient was placed in bed with his shoulders raised, and his head moderately flexed by bandages. At this time, 3 P.M., temperature was 100° F., pulse 85. Patient was given liquid food which he appeared to relish, and his bowels were moved by an enema, while he was also given a saline laxative.

July 26, 10 A.M. Patient slept well preceding night. Bowels moved at 1 A.M. Temperature 100°. Pulse 80. Felt "maitai" (well). There was considerable blowing through the tube, with mucus and blood, so we removed the tube, inserting another in its place. Patient improved daily, his temperature and pulse gradually decreasing until August 1, when both had become normal.

The air came less and less through the wound, and the external opening closed up so quickly that I had to irritate the edges in order not to have it entirely heal up.

In three weeks the wound was healed, the patient eating, sleeping and carrying on other functions as usual.

I was curious to see the result of my suture, but did not consider that I should be justified in opening the external wound to satisfy myself, and so had removed the tube and allowed nature to do its perfect work.

About midnight, August 26th, I was called to the hospital, where I found that our patient had in some way eluded the vigilance (?) of his attendant, got hold

of a jack knife, and ripped open the old external wound, besides inflicting several slight wounds on his abdomen. He had evidently tried to do the Japanese suicide act. Then I was able to look upon my united trachea. It appeared to be as good as ever, and the stitches were fast disappearing. I at once sewed up the flesh-wound, and on the morrow we sent our patient to Honolulu to await his trial.

In the following December he was tried, found guilty of murder on one charge, and sentenced to death, which he met in Honolulu, March 28, 1898. At the trial, Mr. Dole, the prosecuting attorney, expressed his regret that the attending surgeon had seen fit to put the Hawaiian government to so much additional expense.

LEUKEMIA AND SPLENIC PSEUDOLEUKEMIA.*

By EVERETT J. BROWN, M.D.,

of Decatur, Ill.

THE object of this paper is to present two cases of the more common form of leukemia, known as the splenomyelogenous variety (one of which has just come to autopsy), and a third case of the much rarer and very interesting form of disease known as splenic pseudoleukemia or splenic anemia. It is to the latter case that I wish to call especial attention, for although now regarded as a rare disease, yet I anticipate that with the revival of interest which has been created recently in its study by the two papers of Osler,¹ and the critical summary of the literature by Sippy,² and his report of a recent case, many more cases will be brought to light, and its clinical recognition be made easier; in fact, such has already been the effect, and in the issue of the *Boston Medical and Surgical Reporter* for April 26 there appeared three articles on the subject, with the report of four additional cases of the disease.

The leukemias may be divided into two great classes: the *true* and the *false*. Of the true leukemias there are three subdivisions—the lymphatic, the splenic, and the myelogenous; clinically, however, we cannot make this sharp division, for the most commonly observed type is a combination known as the splenomyelogenous variety; of the pure myelogenous form there are only two cases on record, hence its existence may be doubted. The pure lymphatic form, although comparatively rare, is quite often observed, while the pure splenic variety, without lymphatic or medullary involvement, is also quite rare. An acute form of true leukemia is now quite frequently seen, although its proper place in the study of these blood-conditions has been hardly yet established.

Of the false leukemias, Hodgkin and Bonfils (quoted by H. C. Wood³) named two varieties: lymphatic pseudoleukemia, or Hodgkin's disease, and the lymphosplenic pseudoleukemia. Wood (1871) recognized the third variety: the splenic pseudoleukemia. The relationship existing between pseudoleukemia and leukemia is still in doubt, and it is possible that in time they will be found to be only phases of the same disease; they have the same clinical history, the same lesions of solid organs, the same general course, and differ only in the existence or absence of a marked leukocytosis with some qualitative differences in these leukocytes; this similarity, together with the occurrence of leukocytosis during the course of a pseudoleukemia,

* Read before the Illinois State Medical Society, May 18, 1900, at Springfield, Ill.

make one wonder if the diseases are not identical. There is one fact, however, that points very strongly against this supposition, and that is the effect of the operation for the removal of the spleen, which in leukemia is almost universally fatal, while in splenic pseudoleukemia quite a number of successful results are recorded.

Leukemia may be defined as a disease affecting the blood-producing functions of the body, characterized by a marked quantitative and qualitative change in the leukocytes, and by peculiar changes either in the spleen, bone-marrow or lymph-glands, or in all of these structures, running occasionally an acute, but usually a chronic course, and exhibiting a progressive anemia, a marked tendency to hemorrhages and a fatal termination. The pseudoleukemias answer in a general way to the same definition, with this difference, that there is no marked leukocytosis and no peculiar forms of leukocytes. Splenic pseudoleukemia therefore, which is especially interesting us today, on account of this revival in its study, may be defined as a primary splenic hypertrophy with a progressive anemia, without involvement of the lymph-glands and without marked increase in the white blood-cells. For purposes of comparison I will first report the two cases of true leukemia:

CASE 1.—*Spleno-myelogenous leukemia; pregnancy, with abortion at six months, followed by double phlegmasia alba dolens*—Mrs. G., aged 31; a farmer's wife; sent to me on March 14, 1900, with a diagnosis of ovarian tumor; family history negative, no malarial history; has had seven children, four living and in good health. Six months ago she noticed a "lump" in the left side just under border of ribs; it was distinct from the abdominal enlargement due to the pregnant uterus. On January 4, she miscarried at six months, and in one week developed fever, and a week later, phlegmasia in both legs, which continues to the present time. At the time of miscarriage the tumor was the size of a teacup, but since then it has increased steadily in size. No enlargement of lymph-glands. She has had recurring epistaxis, bowel hemorrhage and metrorrhagia. She is somewhat emaciated, pale, with well-marked melanoderma resembling Addison's disease. Temperature 100.5° F., pulse 100. Physical examination shows a large tumor in left side of abdomen. The dullness begins at the ninth rib in the axillary line and merges into the tympanitic sound at a point half way between the last rib and the crest of ilium; the tumor-mass extends to the umbilicus and downward to a point midway between the umbilicus and symphysis; above the umbilicus the dullness is continuous with that of the left lobe of the liver; a distinct notch is felt half way between the ensiform and umbilicus. Spleen moves vertically, not diagonally, with respiration; it is tender on pressure and the heart-sounds are transmitted through it; no bruit; heart apex in fourth space on nipple line; lung-liver border at sixth rib; sternum and tibiae tender on percussion.

Blood examination: Hemoglobin 75%; red cells, 3,600,000; white, 250,000; differential count; myelocytes, 38.5%; polymorphonuclears, 53.3%; lymphocytes, 7%; eosinophiles, 1.2%; numerous nucleated reds, some with double nuclei.

Eye examination made by Dr. S. E. McClelland shows normal vision, but a pale retina, with both fields of vision contracted.

Urinanalysis: Color, yellow; albumin, sugar, bile, indican and diazo negative; chlorids 19%; phosphates 5%; urea 2%; sediment; amorphous phosphates.

May 1. At present writing she has entirely recovered from the phlegmasia, is up and around and able to work, is taking arsenic, and appears much less anemic; spleen remains the same size giving her the appearance of a seven months' pregnancy; she has occasional slight fever, good appetite, epistaxis at times and metrorrhagia when on feet much. Her weight is 136 pounds; in health it was 165 pounds. A recent blood-examination shows: hemoglobin, 70%; white cells, 128,000; in 2,000 there are 12 nucleated reds, all normoblasts.

CASE 2.—*Spleno-myelogenous leukemia, uncontrollable priapism lasting 26 days; nearly fatal epistaxis; death from exhaustion; autopsy*—Jno. C., aged 40; farmer; seen first on September 2, 1899. Father died of gastric cancer; one sister of phthisis. Patient not well for 2 years; noticed spleen enlargement 10 months ago. Has been in bed for 3 weeks on account of the very painful priapism, which is not affected by treatment, but requires the use of the catheter and prevents sleep; a painful urethritis has now developed. Spleen occupies the larger part of the left half of the abdomen; no edema or ascites; patient is very anemic; temperature and pulse normal; no involvement of lymph-glands; no melanoderma. Urine shows a specific gravity of 1.015; albumin and sugar negative; sediment of pus-cells and bacteria.

Blood examination: Hemoglobin, 75%; red corpuscles, 2,940,000; leukocytes, 556,000. Differential count; polymorphonuclear neutrophils, 56%; myelocytes, 41%; lymphocytes, 2%; eosinophiles, 1%.

Eight months later he died; had been up and around most of the time since the attack of priapism which lasted 26 days; he had had several slight attacks of this complication before, but each time it lasted only 6 or 8 hours; at all times there was no sexual erethism. Three days before death he became totally deaf; his vision had been greatly affected for months. Duration of life after discovery of enlarged spleen, 1½ years; total period of ill health, 2½ years.

Autopsy: Eighteen hours postmortem; with the assistance of Drs. W. T. Patterson and Will. Chenoweth. Emaciation not extreme; purpuric spots on arms at site of hypodermic needle punctures; abdomen quite flat, in marked contrast to the enlargement before death; pleurae and lungs negative; pericardium contains 2 ounces of clear yellow fluid; heart not enlarged, filled with semifluid chocolate red blood, valves competent but showing on mitral and aortic leaflets patches of atheroma. Upper third of the greatly enlarged spleen firmly adherent to the diaphragm and to left lobe of liver; it is smooth and uniformly enlarged and its right border presents three distinct notches; it is 15 inches long, 8 inches wide and 3½ inches thick; longer circumference 31 inches; shorter, 19 inches; weight, 10 pounds.

Liver: weight, 7 pounds; right lobe, 8½ by 10 by 3½ inches; left lobe, 9 by 3½ by 2 inches. Left kidney floating, smaller than right. Stomach, intestines, mesenteric glands and bladder normal.

Histology: Spleen, increase of cellular elements. Malpighian bodies indistinct. Leukocytes abundant in lymph spaces and free in stroma. Liver shows slight cirrhosis; capsule thickened, with small hemorrhages beneath; lobules show chronic congestion. Infiltration of leukocytes between liver cells. Kidney: Some increase of connective tissue and atrophy of glomeruli. Hemorrhage into straight tubules. Increase of leukocytes is seen in capillaries and between the tubules.

The third report is the case of splenic pseudoleukemia previously mentioned.

CASE 3.—*Greatly enlarged spleen; profound anemia; advancing to cachexia; no leukocytosis; great ascites and edema; death from exhaustion; autopsy*—C. T., male, American, aged 54; farmer; married. First examined by me in May, 1898. His father is living at 80 years; mother died of heart disease. One brother died at 55 of some abdominal cancer; another brother is living, but has Bright's disease, and one sister is living at 55, but with anemia and some stomach-disease. He belongs to the better class of farmers, being well to do, and from a very intellectual family; his habits have been good; no alcohol, but an excessive user of tobacco; fond of condiments and a good eater; no venereal history. He had a very severe and prolonged attack of malaria 15 years ago.

Present illness: For 3 years he has not seemed well. was irritable and easily tired and at times had backache when standing; has been pale and yellow for over a year; 6 months ago he coughed or spit blood (6 or 7 large mouthfuls), and two or three times later he has done the same, but at no time was there severe hemorrhage; has dyspnea on exertion, and some heart palpitation. Edema of ankles appeared first about 4 months ago, gradually extending up the legs and into the abdomen; more or less cough exists and there is constipation. Examination: A very large man, but having lost considerable in weight; the anemic appearance is

marked. Is up and around most of the time and oversees his farm work; mind is clear and active and in spite of his forced levity one observes in him an intense anxiety as to his disease. Skin is dry and rough and subcutaneous tissues flabby; temperature normal. Pulse 70 to 90. A tumor mass (not large) is felt under the left costal border; ascites and edema considerable. I made a diagnosis of cirrhosis of the liver, from the ascites, moderately enlarged spleen, vomiting of blood, etc. On July 5 he was examined by a Chicago specialist who concurred in a tentative diagnosis of cirrhosis, but mentioned the possibility of malignancy or of pernicious anemia; the blood-count, which was as follows, excluded leukemia. Hemoglobin (Fleischl) 35%; red corpuscles 1,450,000; white corpuscles 6,300; no nucleated reds. Microcytes and macrocytes somewhat abundant.

October 24, spleen is enlarging and is felt as a large firm mass with smooth surface protruding out from under the left costal arch and extending to a point beyond the umbilicus and downward to a point within a hand's breadth of the pubic bone; it moves with respiration in a diagonal direction, its edge is easily felt and the whole tumor can be quite readily grasped with the hands and moved in a lateral direction. Urine 1.020; no albumin. I lost sight of the case for 6 months while I was in Europe, and on my return in June, 1899, all his symptoms were increased: larger spleen, more anemia, more dropsy. Four days before his death his abdomen was tapped and a large quantity of slightly pink fluid removed. Death from exhaustion. Duration of disease, two years and five months.

Autopsy: Eighteen hours postmortem. The subject, a very large man, showed a high grade of emaciation; the subcutaneous fat was greatly reduced, the subcutaneous tissues were edematous, the feet and legs were swollen and the abdomen greatly distended by the ascites and the greatly enlarged spleen. There was no decided enlargement of the lymph-glands either externally or in the abdomen. The ascitic fluid was estimated at 1½ gallons, and when held to the light in a test tube showed a slight pinkish tinge. The organs were only examined in situ, and sections removed from them for microscopic examination. The spleen was greatly but uniformly enlarged, filling the greater part of the left half of the abdominal cavity; the surface was smooth and showed no peritoneal adhesions; the small notch at right border was well marked; the liver was somewhat enlarged and presented a smooth surface and no visible signs of cirrhosis; pancreas, kidneys, stomach and intestines negative. *Histology:* Pancreas, small cell infiltration and postmortem necrosis. Liver: no cirrhosis, but localized collections of lymphoid cells in the capillaries and a moderate atrophy. Spleen: marked hyperplasia of the finer stroma, with collections of lymphoid cells throughout, similar to those in the liver. Throughout the stroma there are also numerous giant cells with nuclei arranged centrally. The above report was kindly made for me by Dr. A. S. Warthin, in Dr. Dock's laboratory at Ann Arbor.

The *Index Catalogue* gives few references under the caption "Splenic Anemia," hence the literature must be sought under several other heads, such as splenic hypertrophy, anemia, Hodgkin's disease, etc., but as far as I have been able to find there are recorded, before the case which I report today, only 51 cases of this disease. The number of autopsies is even smaller, being only 18 recorded. Sippy was able to select from the literature 7 cases in which the spleen had been removed for this disease; of these 5 recovered; since then Osler has reported 1 additional case which terminated in recovery; these excellent results lead one to hope that the operation may be established as a regular procedure in all primary enlargements of the spleen, the main contraindication seeming to be only a great leukocytosis or a far advanced cachexia.

In looking up the literature of this subject it is surprising to see how much the older writers knew on the subject and how much has since been forgotten about it; for years no textbooks mentioned the subject and several of the recent ones have nothing upon it. This

may be due to the fact as Shattuck⁶ recently said, that we are classifying away ahead of our knowledge, and that our ignorance of the so-called splenic anemia is yet great, and that it is not even a clinical entity. Musser⁹ in his latest edition on Medical Diagnosis does not mention splenic pseudoleukemia, but speaks of a secondary or so-called splenic anemia which in no case exists as a primary anemia, but which is distinguished from leukocythemia by the lesser frequency of hemorrhage, by the absence of leukocytosis and by the special characteristics of the leukocytes. As regards hemorrhage, most other observers differ from this opinion and speak of the various hemorrhages as being a special characteristic of splenic anemia. Osler gives a short article on splenic anemia in his textbook and says it is a disease characterized by great enlargement of the organ, profound anemia without leukocytosis and without the coexistence of malaria, rickets, or other states in which enlargement of the spleen is secondary. Yet in his above-mentioned report, which appeared in January, 1900, he includes 4 cases of undoubted malarial history.

Stengel⁸ in his article in the "Twentieth Century Practice" mentions *splenic anemia* under the list of synonyms for Hodgkin's disease, he dismisses the subject in a few lines by saying: "Splenic hypertrophy may be unassociated with changes in the lymphatic glands or other structures. Such cases constitute the splenic anemia of Griesinger and Strümpell, or the splenomegalia primitive of Debove and Bruhl. More commonly the splenic enlargement is followed by some involvement of the lymphatic glands, and the latter may become the more conspicuous feature of the disease." In another place he says that cases spoken of as splenic anemia are widely different in nature, some belonging to the symptomatic anemias, others being cases of Hodgkin's disease.

Sahli,⁶ in his recent *Klinische Untersuchungs Methoden*, recognizes the two pseudoleukemias, viz., pseudoleukemia lienal, and pseudoleukemia lymphatica.

Eichhorst⁷ mentions the three forms of pseudoleukemia—the lymphatic, the splenic and the myelogenous; the first being the more common, the two latter quite rare. He also refers to H. C. Wood's case in 1871.

That some obscure relationship exists between leukemia and splenic pseudoleukemia there can hardly be a doubt, but the fact that surgical intervention in the case of pure leukemia is always fatal, while in the false form it is often successful, makes one believe in their distinct entity.

Sippy gives Banti the credit for first describing the affection in such a manner as to attract the attention of the medical profession. Banti's paper⁴ appeared in 1882, and although of great value, yet it was antedated by our own countryman, H. C. Wood, who described a case in the *American Journal of Medical Sciences* in 1871. Banti gave the following definition of the disease: "Anemia splenica is a disease characterized by a progressive oligemia, arising without appreciable cause, and giving rise to grave disturbances of all the organic functions, causing edemas, hemorrhages, irregular fever and followed constantly by death, and accompanied by a notable tumefaction of the spleen and the liver, which tumefaction is independent of any preceding morbid condition and is not associated with any leukemic alterations of the blood."

A short history of H. C. Wood's case, being the first one described in America, might be of interest.

CASE.—M., male, aged 30 years. Seen in August, 1870. Had served during the last 6 months of the war in a malarial district of Virginia; no distinct malaria, but cough, diarrhea, and dysentery. On returning home he resumed his occupation of confectioner; did much lifting; bowels loose now for 3 years; also pain and dragging in left side; for 2 months gradual loss of strength and flesh. Is now pale; no fever; tongue clean; abdomen enlarged, but free from fluid. Spleen shows dullness vertically $5\frac{1}{2}$ inches, and transversely $6\frac{1}{2}$ inches; surface smooth, hard; edges rounded, tender on pressure. Liver enlarged; vertical dullness $5\frac{1}{2}$ inches; edge 1 inch below ribs; urine normal; slight edema of legs. Blood: no increase of leukocytes. The spleen gradually enlarged, the leukocytes diminished, and he finally died of exhaustion. Postmortem: Spleen 8 by $5\frac{1}{2}$ by 4 inches; color, bright red; masses of yellowish color through spleen; lymphatics enlarged in thorax and abdomen. Spleen pulp contained usual elements.

In making a diagnosis of *true* leukemia the blood-examination tells everything, while in the pseudoleukemias it furnishes only negative evidence, for as yet we have found no distinctive quantitative or qualitative change in either the white or red cells; in leukemia, however, as is well known, the leukocyte count usually passes the 100,000 mark, and lymphocytes or myelocytes are more or less abundant according to which form of the disease exists. Osler has already called attention to the remarkable attacks of hematemesis in cases of enlarged spleen, whether primary or secondary; in his 15 cases of splenic pseudoleukemia, 8 had had hematemesis; in 7 of these this was the symptom for which they sought relief, and in 2 it was the cause of death. Sippy's case had repeated epistaxis; the cases operated upon by Pean showed hemoptysis, hematemesis, hematuria, and bloody stools; in fact, in reading the histories of most cases of the leukemias one is struck with the frequency with which we find some form of hemorrhage; my case of splenic anemia had hemorrhage from the stomach, and the case of splenic leukemia which I have reported above in a woman gives a history of epistaxis, metrorrhagia, and bloody stools.

I am indebted to my assistant, Dr. C. Martin Wood, for valuable aid in studying these cases and in searching the literature of splenic anemia.

SUGGESTIONS ON THE TREATMENT OF WHOOPING-COUGH.

By H. F. THOMPSON, M.D.,

of Buffalo Center, Ia.

WHOOPING-COUGH is an acute infectious disease, occurring chiefly in children, characterized by paroxysms of cough in rapid series, threatening suffocation, terminating by a long-drawn audible inspiration, and accompanied by more or less nasal, laryngeal, and bronchial catarrh.¹

While the exact cause of whooping-cough has always been a matter of doubt it is now generally accepted to be of microbic origin, the only question being the identity of the microorganisms. It seems fairly certain from numerous observations, both clinical and experi-

mental, that such is the case, and that the specific microorganism generates a toxin having a selective action on the center of the vagus and superior laryngeal nerves.

It has been proved experimentally that the superior laryngeal nerve is the nerve of cough, and any irritation of the areas supplied by this nerve, as the posterior laryngeal wall, just below the vocal cord, and the trachea to its bifurcation, produces most intense cough.

Von Herff,² in studying the disease as it occurred in himself, observed a marked congestion of the mucous membrane of the under surface of the interarytenoid folds, with small deposits of mucus, especially on the posterior laryngeal walls. He thought that the removal of these deposits of mucus aborted the attack. But be the etiologic factor what it may be, the fact remains that whooping-cough is essentially a self-limited disease; that the etiologic factor is self-destructing, or that it eventually succumbs to that well-known process present in all animal organisms, leukocytosis, phagocytosis, or what not, remains to be proved. The fact that for generation after generation, children have been afflicted with whooping-cough, a large percentage of them having recovered eventually without medication of any kind at any stage of the disease, proves the self-limitation of the affection.

The etiology, pathology, symptoms, and complications are of small importance when compared with the treatment. That the treatment of whooping-cough has resulted in many failures and much disappointment, is proved by the large number of drugs that have been tried. Until the etiologic factor can be demonstrated to an absolute certainty, treatment must be empirical. The symptoms as they arise, and the conditions as they present themselves, must be met and treated *secundum artem*.

It has been my good fortune to have a few cases of whooping-cough under my care of late, all of which I have treated with heroin, and it is with a view of calling attention to this drug in the treatment of this disease that this article is presented.

In heroin we have a valuable therapeutic agent which allays cough and eases respiration. It reduces the number of respirations, but increases their force and the volume of inspired air. The current literature is full of praise of its value in the treatment of pulmonary tuberculosis, bronchitis, asthma, laryngitis, and other affections of the air-passages. Aside from its almost specific effect in relieving cough, which has now been fully established, heroin also exerts a distinct influence in allaying dyspnea. The first to call attention to this action of the drug was Professor Leo,³ who employed heroin in various conditions attended with dyspnea, and found that it acted promptly and without the least depressing action upon the heart.

As to the use of the remedy in the treatment of whooping-cough, I find that Dr. A. Holtkamp⁴ reports 5 cases in children of 2 to 7 years of age. The drug was given guardedly in doses of $\frac{1}{150}$ to $\frac{1}{135}$ of a grain, usually three times daily. Under its administration the attacks were diminished both in severity and frequency. Floret⁵ describes three cases of whooping-cough in children respectively 3, 4, and 8 years old. The doses administered varied from $\frac{1}{15}$ to $\frac{1}{16}$ grain. It was always well tolerated, and rendered the attacks much more infrequent and less violent. There was also improvement of the general condition of the patients. In two other cases referred to by the author

the remedy failed to act, which is attributed by him to the administration of too small doses. Medea⁶ found heroin less useful in whooping cough than in other affections of the respiratory tract. On the other hand, Manges⁷ states that whooping-cough has been very favorably influenced by heroin. The drug was very well borne, and the paroxysms were shortened in 25 out of 33 cases.

Heroin has been found to be beneficial to a greater or less extent in all stages of pulmonary affections, but the best results were obtained in the more acute cases, in which it promptly produces free expectoration and freedom from cough and pain.

Referring to the statement made by von Herff that the removal of the deposits of mucus on the posterior laryngeal wall aborted the attack, the action of heroin renders this removal easier, by allaying spasm and causing the mucus to be more easily expectorated. Thus, in a nutshell, we find explained the beneficial action of heroin in whooping-cough. The mucus accumulates on the posterior laryngeal wall supplied by the superior laryngeal nerve (the nerve of cough), irritating this nerve and producing most intense cough. If these paroxysms can be aborted by the removal of the mucus from this area, we render the patient less liable to fall a victim to the serious complications of the second stage, and from the antispasmodic and expectorant qualities of heroin we get the desired results.

CASE 1.—A. V., aged 20 months, was first seen April 2, 1900. She had a severe cough, ending with a characteristic "whoop," and usually accompanied with vomiting. Temperature 101° F. I gave heroin, $\frac{1}{8}$ grain, every four hours, and ordered warm baths for the temperature. April 3, the patient coughing less, but quite drowsy. The bowels not having moved, hydrarg. chlor. mit., $\frac{1}{4}$ grain, was administered every three hours until 1 grain had been given. Heroin was continued for 4 days at intervals of 4 to 8 hours, with complete disappearance of the cough, and no unpleasant complications.

CASE 2.—James G., aged 4 years, had been suffering with pertussis for 4 weeks prior to coming under notice. I was told by his father that he had been very bad. He had learned to assume a position on his knees and hands when the paroxysms came on. He had several attacks each day, and seemed to be worse at night. Heroin, $\frac{1}{24}$ grain, was given every four hours for several days, with a rapid amelioration of the symptoms.

CASE 3.—Mrs. G., mother of patient in Case 2, said that she took several doses of the heroin at irregular intervals, and was benefited very much. She had a severe attack of pertussis, and, like her son, suffered most at night. The symptoms subsided, and she is now entirely free from the cough.

CASE 4.—Lloyd C., aged 15 months, had been suffering with spasmodic cough for 3 months, and vomited several times daily. He was given heroin, $\frac{1}{24}$ grain. Four doses stopped his cough for several days. July 3, he had another attack with vomiting. Heroin ordered to be continued, $\frac{1}{24}$ grain, three times daily, the result being prompt disappearance of all symptoms of whooping-cough.

CASE 5.—M. C., father of patient in Case 4, aged 27, began taking heroin, $\frac{1}{24}$ grain, after having pertussis one week. He had been unable to sleep because of the almost constant cough, accompanied with severe retching. He was given the first dose at 6 P.M.; took another at 10 P.M., and experienced relief at once. In all he took 6 $\frac{1}{24}$ -grain tablets, and is entirely free from cough and sleeps well.

RE-EXPANSION OF THE UTERUS IN LABOR.

By D. BENJAMIN, M.D.,

of Camden, N. J.

Obstetrician and Gynecologist to the Cooper Hospital; Lecturer on Obstetrical Nursing in the New Jersey Training School for Nurses; formerly Chief of the Department of Diseases of Women and Children in the Camden City Dispensary; and First Assistant in the Department of the Nervous System and Brain in the University Hospital, Philadelphia, etc.; Member American Medical Association.

I HAVE come to the conclusion that *the parturient womb during any stage of labor and for a few hours thereafter can be expanded to about the same size as it was when labor began.* This was demonstrated as early as 1884.

When I had arrived at this conclusion, as a process of reasoning and investigation, I had occasion to try it in practice, and I have repeatedly demonstrated at the bedside its practicability, when necessary. An appreciation of the importance and truth of the foregoing proposition enables us to open a very valuable field of practice and introduce a number of exceedingly valuable and important procedures or operations based on

FIG. 1.—Actual measurements of child delivered.

it. These will be referred to in the treatment of the complications and malpositions in which they are applicable. We have been taught that the forces of parturition when thoroughly aroused and in vigorous normal action can not be stayed by the hand of man to any great extent; that the contracting and expulsive efforts of nature force the child with progressive energy against the superior strait or into the pelvis with great power and firmness, and that as a rule with the exception of a brief period after the escape of the liquor amnii, little can be done in the way of releasing and manipulating the impacted head. Nevertheless from extensive observation, I believe that the uterus can be re-expanded, and the child's head returned above the superior strait, and converted into a favorable position from any unfavorable one, thus frequently avoiding craniotomy or cesarean section. This becomes more important when we consider that podalic version is seldom justifiable, for a head that can not be delivered by the vertex, when presenting, cannot be delivered by the feet.

METHOD OF REEXPANSION AND RETURNING THE CHILD'S HEAD.

We will suppose, for instance, an extreme case in which the head has passed through the superior strait, and has become impacted low down in the pelvis in such a position that it cannot escape through the inferior strait. Anesthetize the patient, bring the hips close to the edge of the bed, elevate them well above the level of the patient's shoulders and put an assistant in charge of each leg. Having bared and sterilized your

FIG. 2.

arm and hand, and applied sterilized cosmolin, begin making firm pressure with the palmar surface against the presenting portion of the head in the direction of that portion of the axis of the pelvis occupied by the head; return it by exactly the route and flexions that it came, making firm, steady pressure between the pains and holding every fraction of an inch gained when the pain comes on until it is over. It will be found to give a little between each of the pains. The process is often a long and laborious one, and since the hands and arms are apt to tire out, advantage must be taken of each opportunity to rest them without losing ground, such for instance as propping the elbow against the knee, and foot against the wall, or in any other manner to take the strain off the muscles, and by occasionally changing hands or being relieved by an intelligent assistant. The womb will not only begin to elongate upwards, but will seem to relax its efforts, so much so, that the nurse standing by will sometimes exclaim "the pains have left her," thus, gradually the head returns above the superior strait, making room for all purposes. You can now pass your hand around the child's head in all directions, and absolutely confirm your diagnosis of the position, removing the cord from its neck in the womb, if necessary; or turning the body of the child, you can firmly grasp the head and turn it in the desired direction, assisted by the other hand on the outside of the abdomen.

TREATMENT OF FACE PRESENTATION WITH THE CHIN POSTERIOR.

This most hopeless and dreadful condition unfortunately is of frequent occurrence and has heretofore baffled obstetric science; Professor H. L. Hodge, mas-

terful in the principles of practice, summed up the situation in the matter up to his time (1864) as follows: M. Caseaux, also, denies the possibility of deliveries, under these circumstances, "at term," and he considers them as constituting one of the most serious difficulties of the obstetric art. In truth, the child and mother would perish without scientific assistance.

Should, however, the head be comparatively small, and the perineum greatly relaxed, spontaneous delivery, with the chin posterior is said to have occurred in the practice of Smellie, DeLamotte, Guillemot and others. This process, however, is greatly resisted by the pressure of the chin against the posterior perineum; and it cannot be fully accomplished without such distention of the perineum as to allow the whole occipito-mental diameter, measuring 5 inches, to intervene between the perineum and the symphysis pubis.

It is evident, therefore, that no such deliverance can be effected, unless the child's head be unusually small, and the soft parts relaxed.

When the usual natural proportions exist of mother and child Professor Hodge found it necessary to resort to craniotomy which was at that time preferable to cesarean section.

Nor has there been any improvement in the treatment of this presentation promulgated by any of our authorities up to the present time: Lusk disposes of the subject in 1893, important as it is, in these lines, viz: "In mento-posterior the rotation of the chin to the front by repeated applications of the forceps is inadmissible. In

FIG. 3.

practice such efforts do not succeed, while they are calculated to inflict injury upon both mother and child. Usually, if delivery becomes necessary because of danger to the mother, craniotomy should be resorted to."

Grandin and Jarman, whose excellent work has recently been issued, say: "If the chin is turned posteriorly and the head is wedged in the pelvic outlet, there is little probability that a living child can be extracted, that it seems to be part of conservative treatment to turn the attention to the welfare of the mother and do

craniotomy, or, in favorable cases, symphysiotomy." (Obstetrical Surgery, page 87.)

The most recent writer, G. Ernest Herman, advises to make an attempt to twist the chin around to the front, as follows:

"Grasp the face with the thumb and forefingers. Turn it around by the shortest route so as to bring the chin to the front. At the same time, with the hand on the abdomen, press the anterior shoulder in the same direction." Failing in this he advises craniotomy.

In an attempt to turn the chin around to the front, which should be tried, you must remember what is usually lost sight of in this presentation, that the axis of the upper vertebrae of the neck is at a right angle to the axis of the trunk and lower cervical vertebrae.

It seems to be universally admitted by the profession today that the presentation under consideration generally means death to the child or cesarean section in some of its forms for the mother. It is, therefore, with profound respect for other authorities and deference to the profession that I venture to take a different position and offer a more satisfactory solution of the problem not only theoretically but by practical demonstration. Applicable also to similar presentations, it is simply this: Push the head up out of the pelvis and convert it into an occipitoanterior presentation of the vertex, according to the rules given above under method of reexpansion of the uterus and returning the child's head. To prove the possibility of doing this let me cite the following typical case:

Mrs. — was taken in labor on October 9, 1884, it being her seventh confinement; all the others being normal, she was attended by a midwife as had been her custom. After being in labor 3 days Dr. G. W. Henry was sent for; after 4 hours' work finding delivery impossible he sent for his associate, Dr. Jesse Wills. After 4 more hours of fruitless endeavor in which strenuous efforts were made to perform version; to rotate the chin forward, and also to pull the child through by main strength and the forceps, under ether, I was sent for. I found the woman still in vigorous labor; she was medium-sized, and of normal proportions; her general condition was good considering the length of time she had been in labor. Locally the parts were swollen and congested; the membranes had been ruptured 24 hours and the water had escaped. The head of the child had passed through the os and was firmly impacted in the pelvis, chin in the hollow of the sacrum. One of the eyes was greatly swollen from efforts at assistance. The child was alive and above the average in size.

I had the patient placed under the influence of chloroform and found that I could not rotate the head to the front nor deliver by the application of the forceps and downward traction.

I then explained to my colleague what I proposed to do, and proceeded in detail as in reexpansion of the uterus. In one hour I succeeded in raising the chin out of the pelvis, flexing it to the sternum, and delivering with great ease in the O. A. position, vertex presentation. Below are given the dimensions of the head. The child, a fine-looking boy weighing a little over 10 pounds, is living and well, and the mother also.

This method has the superlative advantage of saving the life of the child with less risk to the mother than any other procedure.

Intestinal Catarrh of Infants.—Cohn (*Annals de Médecine et Chirurgie Infantile*, No. 24), in speaking of the employment of silver nitrate in intestinal catarrh of infants, prefers **protargol** in children that are anemic, more advanced in age, and with sensitive stomachs. [M. R. D.]

THE DISINFECTION OF INFECTED TYPHOID URINES.²

By NORMAN B. GWYN, M.B.,

of Philadelphia.

In previous communications I have spoken more fully on the presence of typhoid bacilli in the urines of typhoid-fever patients. Let me briefly review the work which seems to make imperative the disinfection of all such urines, unless proved bacteria-free by careful bacteriologic examination. As early as 1881, Bouchard claimed to have isolated typhoid bacilli from the urines of 50% of cases of typhoid fever; other writers, Hueppe, Seitz, Konjajeff, Karlinski, Neumann, Borges, de la Faille, gave less alarming but positive results. Blumer, Wright, Besson, and Petruschky confirmed the work of the earlier workers, while T. R. Brown, Houston, Horton Smith, Richardson and myself have contributed to the subject within the last 2 years. In this country, Richardson's important collection of 25 cases, and my own 10, show how frequently typhoid bacteriuria may occur.

The general conclusions deducible from most recent investigations may be thus tabulated:

1. In from 20% to 30% of cases of typhoid fever typhoid bacilli may be present in the urine.

2. When present they are usually in pure culture and may be so numerous that the urine is turbid when freshly voided, one of Petruschky's cases showing 170,000,000 bacilli in 1 ccm. of urine; one of our own showing 500,000,000 per ccm.

3. Appearing generally in the second and third week of illness, the organisms may persist for months or years. In Houston's case the bacilli had been for 3 years in the bladder, in one of our own bacilli were found in the bladder 3 and 5 years subsequent to the attack of typhoid fever.

4. Though often showing evidence of cystitis and marked renal involvement, the urine containing bacilli has usually only the characteristics of a simple febrile urine, the presence of the bacilli has no prognostic import, and they may persist for some time without causing local change, multiplying in the urine which remains persistently acid.

The danger of infection from infected typhoid urine must be clearly evident from these facts, if one but remembers that a few drops carelessly spilt may mean, and often does mean, the distribution of millions of typhoid bacilli. The daily number voided in cases in which 170 or 500,000,000 organisms are present in a cubic centimeter, is beyond comprehension.

It is more than probable that urine, by reason of its apparent harmlessness, plays and has played the most important part in the spread of typhoid fever, and, unless we can prove that a patient's urine is free from infectious material, we commit a great folly in letting it be disposed of without disinfecting it, especially when we systematically disinfect the feces, in which the number of typhoid bacilli is small as compared to the number in the urine. When we consider also that many cases may go on distributing the millions of bacilli daily for months, and sometimes, as in the above-mentioned cases, for years, the seriousness of the problem is apparent.

Recently I have investigated the ordinary methods of disinfecting excreta, endeavoring to ascertain the minimum amount of disinfectant necessary for com-

²Read by invitation, October 24, 1900, before the Philadelphia Academy of Medicine.

* Read before the Michigan State Medical Society, at Mackinaw, July, 1900.

tion was greater than that of diphtheria, croup, typhoid fever, scarlet fever, measles and smallpox combined. The fifty-seventh annual report of the Registrar-General of Great Britain shows that the annual death-rate from tuberculosis for the 20 years preceding was something over 67,000. According to the census report there were 103,188 deaths from consumption in the United States in the year 1890. However, owing to the fact that thousands of cases of tuberculosis recover every year, and that many who have the disease die from other causes, and also because many cases are not diagnosed during life, it is only by postmortem examinations that we get anything like a correct estimate of the extraordinary prevalence of this disease in the human race. Such examinations show that consumption is much more common than it is generally supposed to be. In 4,250 successive autopsies in Breslau in 1893, gross macroscopical lesions of tuberculosis were found in 1,392, or about one-third of all cases coming to the postmortem table from all causes. Biggs, of New York, found characteristic lesions in the lungs alone of 60% of his autopsies, and Vrouardel found microscopic evidences of tuberculosis in 75% of his cases at the Paris morgue. Since many cases show lesions that can be seen only with the microscope, it is evident that we can scarcely overestimate the frequency of the disease. Exceedingly interesting statistics on this point are contained in an article by Otto Naegeli in the May number of *Virchow's Archives*. From the results of 500 autopsies made between November, 1896, and March, 1898, in the Pathological Institute of Zurich, he concludes as follows:

1. Tuberculosis during the first year of life is very seldom found.
2. From the first to the fifth year it is infrequent, but almost regularly fatal.
3. From the fifteenth to the fourteenth year one-third of all bodies are found to be tuberculous.
4. From the fourteenth to the eighteenth year tubercular lesions, active or latent, are found in one half of all autopsies.
5. From the eighteenth to the thirtieth year 97% of all sections show tubercular changes.
6. After the thirtieth year, on careful search, indisputable evidence of tuberculosis is found in over 99% of all autopsies.

Surely Osler is right when he says that epidemics are the only great sanitary reformers. Two thousand eight hundred and twenty-six times as many people died from tuberculosis in the State of Michigan in the year 1898 as from smallpox, yet a single case of the latter disease will arouse a whole community, and 25 mild cases of smallpox, with 2 deaths, such as we had in Grand Rapids recently, will almost give a city of 100,000 people hysteria. But no comment whatever is excited by the fact that 117 people died from consumption in Grand Rapids during the past year, being two and a half times the combined deaths from all other infectious diseases. Here, then, is a disease which is constantly with us, manifestly transmissible, and which attacks at one time or another almost every member of the human race, but concerning which the medical profession shows a neglect of sanitary laws which is almost criminal.

A point of interest in this connection, however, is that there seems to be throughout the world a gradual decrease in the death-rate from tubercular diseases, and the results of Naegeli's autopsies show that a large per-

cent of cases recover. His conclusions on this point are as follows:

1. Before the eighteenth year recovery from tubercular lesions is infrequent.
2. In the third decade one-fourth of all cases show tubercular changes that have completely healed.
3. In the fourth decade two-fifths of all cases show lesions in which recovery has taken place, and from then on the number of healed cases gradually increases until it reaches three-fourths of all cases at the age of 70 years.

In England, from 1851 to 1895, the mortality from all forms of tubercular disease was reduced 45%, and from the *pulmonary* form the disease in mortality was still more remarkable for the same period, being about 48%. In Scotland, between the 5 years 1870-74 and the 5 years 1890-94, the decline in the death-rate from tuberculosis amounted to 41%. In Massachusetts the mortality fell from 42 per 10,000 inhabitants in 1853 to 21.8 per 10,000 inhabitants in 1895. A somewhat similar decline in the death-rate from consumption has taken place in New York City, *i. e.*, from 3.79% in 1886 to 2.58 in 1896. Coming to our own State, we find that the number of deaths from consumption has diminished from 112.1 per 100,000 inhabitants for the 5 years 1870 to 1874 to 97.3 per 100,000 inhabitants for the years 1892-96, this being the last group of 5 years the statistics of which are as yet available for comparison—a decline of 12.2%.

But this remarkable reduction in deaths is not limited to tubercular diseases, for statistics show that the mortality from all sorts of infectious diseases has decreased in recent years all over the world. In Michigan the mortality from scarlet fever for the last 20 years has diminished 90%, from typhoid 43%, measles 60%, smallpox 70%, and whooping-cough 44%. There is, however, one striking exception to the decrease in the death-rate from tubercular affections, *i. e.*, *tabes mesenterica*, a disease to which infants are peculiarly susceptible. Between the years 1851 and 1895 the mortality in England from this disease for people of all ages diminished almost one-half, but for the same period for infants under one year of age it increased no less than 27.7%; and while, as just stated, in the State of Michigan the mortality from consumption has diminished 12.2% for people of all ages during the years 1870-96, that from *tabes mesenterica* increased 80% for infants under one year of age. It is quite likely also that a good many deaths from this disease are ascribed to marasmus, chronic gastrointestinal disease, malnutrition, weakness, etc. The great prevalence among infants of this disease is also shown by the frequency with which its lesions are found in postmortem examinations. In an analysis of 127 fatal cases of tuberculosis in children by Ashby & Wright, *tabes mesenterica* was found in 79%. In Woodhead's 177 cases of fatal tuberculosis in children, disease of the mesenteric glands was found in 100. In 155 autopsies on tuberculous children dying in the Manchester Children's Hospital it was found that the lungs were affected in 91% and the mesenteric glands in 65%. A careful examination was made to determine as nearly as possible by which road the infection had gained access to the body, and the conclusion was reached that in at least 50% of the cases the lungs or bronchial glands were first affected, and that in at least 12 or 13% the abdominal organs were primarily affected, making it probable that the disease obtained access to the body

through the intestinal canal. Purban states that in 165 cases of peritoneal tuberculosis examined after death, 53% were attributed to intestinal infection. As a considerable proportion of children suffering from tubercular peritonitis or disease of the mesenteric glands recover, these figures do not adequately represent the proportion of children so affected.

This great increase of tuberculosis of the intestines and adjacent glands in children at a period of life when the powers of resistance of the organism are at their lowest is very suggestive of the existence of an infective agency in children which is not found in adults, and as the only vehicle by which primary tubercular infection can be conveyed to the digestive tract of infants is found in their food-supply, we are forced to the conclusion that milk, which forms such an essential part of the food of infants, is to them a frequent source of infection. Moreover, the last few years have demonstrated that tuberculosis is common in dairy cows, and more particularly in Jerseys. Of 4,093 cattle in Massachusetts tested for tuberculosis, 1,081, or 25%, reacted positively to tuberculin. These were killed and anatomical evidences of tuberculosis were found in all but 2. Amongst dairy cattle, at the present time, it has been estimated that at least 25% are more or less affected with tuberculosis. This estimate is based upon the results of postmortem examinations of herds of cattle which have been slaughtered under the pleuropneumonia regulations in England and of observations made in public slaughter-houses. Where the tuberculin test is used the percentage of animals affected is considerably higher. Tubercle-bacilli are *generally* found in milk when tuberculosis of the *udder* is present, and such milk is said to possess a virulence which can only be termed as extraordinary. The experiments of the Royal Commission of 1890 in England are exceedingly interesting in this connection. When guineapigs are fed on meat which was intentionally contaminated with tubercle-bacilli, only a few developed the disease, but when they were fed milk from tuberculous udders all became infected.

The milk of an animal suffering from tuberculosis may also contain tubercle-bacilli and be capable of communicating the disease when no demonstrable disease of the udder is present, and bacilli are no doubt present in a fair percentage of milks on the market. Obermüller found that 10% of guineapigs inoculated with ordinary market milk became tuberculous, and 30% of those inoculated with ordinary market cream. In many instances the udder shows no perceptible disease; in fact, tubercular disease in such a bulky organ may be impossible of recognition on physical examination, and in its early stages is most difficult to diagnose. Nor does an examination of milk for bacilli present an infallible solution of the problem, for they may be present at one time and absent at another. Sidney Martin examined the milk of 5 cows which turned out to have tuberculosis of the udder, and could find tubercle-bacilli in but 3. Fifteen test animals were fed with the milk that contained bacilli, and tuberculosis was produced in each one; the milk of the 2 cows which had tubercular udders, but in whose milk no tubercle-bacilli could be demonstrated, was fed to 12 test animals, and 4 of them developed tuberculosis.

Tubercular bacilli have also been found in butter and cheese. That gastric juice exerts any influence upon them under natural conditions is extremely doubtful, as these organisms can resist it from 5 to 6 hours out-

side the body. Under natural circumstances the bacilli would have a still better chance of escaping unharmed, the gastric juice being diluted and the bacilli being often coated with food and more or less protected in this way.

I wish also to call attention to the possibility of contracting other forms of tuberculosis than the intestinal from infected milk. Welch states that postmortems show that 40 to 80% of all cases of pulmonary tuberculosis have also intestinal disease. Nor is it possible in all cases to tell which is the primary and which is the secondary lesion. He also says that tubercle bacilli may enter the body without leaving behind any lesion at the point of entrance. Hence, is it not impossible to deny that a much larger proportion of cases of the pulmonary forms of the disease may be due to infection from the gastrointestinal tract than is commonly supposed?

In view of these facts does it not seem that the State which does so much to prevent the spread of other infectious and communicable diseases should do more to limit the spread of this fatal disease by preventing the sale of milk from tuberculous cows?

The exclusion from dairies of every cow which has demonstrable disease of the *udder* only would form some approach to security; but as tubercle bacilli have so frequently been found in the milk of cows which are free from udder disease, and as such disease is so difficult of recognition in its incipency, I believe that all cows responding to the tuberculin test are possible sources of danger, and that the sale of their milk should be prohibited. The State should pass laws compelling the systematic inspection of all dairies and cowsheds within its borders, and of all animals whose milk is placed on sale. Regular tests with tuberculin should be made, and the sale of any milk from a dairy wherein a tuberculous animal is found should be prevented by a prohibitive penalty until such animal is excluded from the herd.

This does not mean by any means that all such animals should be slaughtered, for the method of treating tuberculous herds which has been worked out by Professor Bangs, the Government Veterinarian of Denmark, and which has been thoroughly tried in that country as well as in parts of our own, shows that the disease can be "weeded out" in a practical manner. The sale of reacting animals should be prohibited, except for immediate slaughter, which should be done under authorized veterinary control, it often being possible to use the meat under certain conditions. Neither statistics nor experience would seem to indicate that tuberculosis is communicated to any great extent through the agency of meat, for the greatest diminution in the death-rate from tubercular disease occurs at those ages when meat is most largely consumed, and we know that tubercular deposits are very seldom found in those portions of a carcass which are sold for food. It has been found that only rarely does the tubercle bacillus lodge in the muscular substance of a carcass, and, providing the organs containing the tubercular deposits are destroyed, the meat itself may be sound.

For a long time it was believed that the only effective way of preventing the spread of tuberculosis in an infected herd was to slaughter all animals that reacted to the tuberculin test, but it is now known that animals affected in the earlier stages, which are kept under favorable hygienic conditions, will live frequently

for years without the disease making any apparent headway, and the progeny of such animals is scarcely more liable to tuberculosis at birth than that of non-reacting animals. Such calves have in all cases at the Wisconsin Agricultural Experiment Station stood the tuberculin test without reaction, showing that tuberculosis in cows is contracted *after* birth, rather than *inherited* from diseased mothers. If such calves are removed from the infected atmosphere, placed under good hygienic surroundings and fed on milk free from tubercle bacilli, they will not show any taint of disease. Treated in this manner, the labor of years spent in careful and selected breeding and the large money values involved are not needlessly destroyed.

To one who is at all familiar with the ordinary country dairy it is evident that some supervision of the construction and management of cowsheds is a reform which is urgently called for, as experience shows that the amount of tuberculosis in cows is very materially diminished by sanitary surroundings, and I am very glad to say that the State Board of Health of Michigan is required by law to pass upon the plans and specifications of all buildings wherein cows are kept in connection with all State institutions.

Moreover, inasmuch as tubercular infection in cows is supposed to take place mainly through the inhalation of dried sputum, no individual suffering from pulmonary consumption should be employed in any capacity in or about barns, dairies, or milk wagons.

Tubercle bacilli are very seldom inherited. The germ may pass from a tuberculous parent into the body of a fetus which may then be born with a tubercular lesion, but this has been seen so rarely that it simply enables us to affirm that the inheritance of the bacillus is not impossible. Osler says that there are now about 20 cases of congenital tuberculosis in man on record. So that for all practical purposes the sanitarian is bound to consider that tuberculosis is not an hereditary disease, but that every case arises under circumstances which can in a great majority of instances be theoretically if not practically prevented. In this connection I wish to quote the conclusions of the recent congress of experts at Berlin.

1. Tuberculosis is a communicable disease, due to Koch's tubercle bacillus acting on an organism prepared to receive it or unable to resist the bacilli when present in large numbers.

2. Tuberculosis is not to any great extent hereditary.

3. Tuberculosis may be prevented by removing the source of infection, by improving the environment, and by strengthening the individual.

4. Tuberculosis in many of its severe varieties can be cured.

These propositions may now be accepted as scientific truths. In certainty they may take rank with the laws of gravitation.

Although tuberculosis itself is seldom hereditary, there is a certain type of structure which has marked hereditary characteristics on account of which feeble resistance is offered to the invasion of the tubercle bacillus. The relative importance of the *soil* as compared with the *seed* has been much discussed. In times past, before Koch's discovery, the tuberculous or strumous diathesis derived from inheritance was considered to play a very important part in predisposing to tuberculosis, and we are now also certain that such is the case. Experience teaches that vulnerability or predisposition to consumption runs in families. The

same is true of measles, scarlet fever, and other infectious diseases. This individual or family susceptibility may be either inherited or acquired, and it is not always easy to distinguish between the influence exerted by heredity and that exerted by bad food, exposure to cold, foul air, and other conditions which lower vitality and render the individual a ready prey when infected.

There can be no doubt that some infectious diseases, as measles and whooping-cough, predispose to tuberculosis by rendering certain groups of lymphatic glands, such as the cervical and bronchial, a suitable soil for the propagation of the specific bacillus. Predisposition may pertain to the individual only or to an entire race, and it is well known that tuberculosis at the present time is much more prevalent among the colored people of the South than among the whites.

The communicability of pulmonary tuberculosis is now so thoroughly established and so generally recognized by the medical profession that I will not take up your time with any arguments upon this point. Statistics show that about three-fourths of all deaths from tubercular disease are due to consumption, and it is generally believed that almost every case is caused by the inhalation of tubercle bacilli, the most frequent source of which is the expectoration of consumptive individuals. Sir William Broadbent echoes the sentiments of sanitarians throughout the world when he says that the prevention of the spread of consumption from persons suffering from the disease resolves itself into the destruction of the sputum, which we know retains its virulence for long periods of time. Outside the body the bacilli are found most frequently in the dust of rooms which have been frequented by tubercular patients, and it has been repeatedly shown that dust collected from hospital wards, asylums, prisons, hotel bedrooms, private houses, etc., where consumptives have been, is capable of producing the disease in animals. Such dust may retain its power for producing tuberculosis for weeks or months. In ordinary breathing the expired air is free from bacilli; when talking, however, there is an invisible spray constantly emitted from the mouth which has been shown to contain tubercle bacilli. This is more apt to be the case in forcible talking, hawking, spitting, etc., and Flugge thinks this spray is a greater source of danger than the dried sputum. Experiments made by directing a fine spray containing bacilli towards the nostrils of animals have produced tuberculosis in them, and some weight should be attached to this point. But tubercular sputum sprayed into the air in this manner subsides at once, and could only infect when coughed into the face of someone and actually mixed with the inspired air. Otherwise the sputum must be dried and broken up into dust in order to be inhaled.

The most important sanitary measure of value in the prophylaxis of pulmonary tuberculosis, but I do not believe that proper measures for the suppression of this disease can ever be enforced until the public in general, and especially that portion of the people who either has the disease or is intimately associated with those suffering from it, become properly educated on the subject. And here I wish to state emphatically that I do not mean *alarmed*, but *educated* in a rational way; and it is for the purpose of enabling this to be done that I believe the State should insist upon the compulsory notification of every case of tuberculosis within its borders. If good is to be accomplished, it is not to be by starting a panic, but by giving the people such a knowledge of

this dangerous disease that they will know themselves exactly wherein the danger lies. It should be impressed upon them that this is principally in one direction, namely, the sputum. It should be constantly kept in mind that it is the sputum, and the sputum alone, that is chiefly concerned in the spread of consumption.

I think there is too great a tendency to the use of the word "contagious" in this connection, as it gives rise to needless alarm. The word transmissible or communicable is much better and is far less disturbing to the public. The minute you use the word "contagion" in connection with a disease, the mental image formed is always that of *acute* contagion such as exists in smallpox, scarlet fever, measles or mumps. But consumption differs from these diseases in this important particular, that whereas in the latter infection is almost entirely beyond the control of the patient, in pulmonary tuberculosis it is limited to the sputum, the disposal of which can very easily be controlled.

While consumption is always the result of infection, it is far less readily communicated than the diseases just mentioned which are transmissible from individual to individual by immediate or direct contact, and for which the word contagion should be reserved. The popular idea of a contagious disease is one from which there is no sure escape except by keeping away from it. When you proclaim a disease to be contagious the people will pay no attention to the conditions of safety which you may lay down, and social ostracism is sure to follow. Isolation, however, or any form of personal restraint upon consumptives who will faithfully carry out the few simple measures for rendering their sputum innocuous, is entirely unnecessary, for with these precautions there is practically no danger from even *intimate* association with such people.

The most certain method of getting correct information as to the etiology, dissemination, and prevention of consumption into the hands of the people who most need it, is for each and every case of tuberculosis to be reported to those whose business it is to look after the sanitary affairs of the State. As far as *immediate* prevention itself goes, the notification of the pulmonary form of the disease alone would suffice. Several forms of tuberculosis, such as hydrocephalus and meningitis, cannot be called infectious in any sense. Neither can tuberculosis of glands, bones, and joints communicate the disease until a discharge is established. But in order to enable us more thoroughly to study its life-history and manner of dissemination, all forms of tuberculosis should be brought to the notice of the health authorities.

The people must be taught that consumption is by no means a necessarily *fatal* disease, but that on the other hand, the large majority of cases, if taken in time, can be cured. It is to the interest of both the patient and his healthy neighbor that the former be informed of these facts. Postmortem examinations show that from 40 to 80% of cases of consumption have also intestinal lesions, and the chances of recovery are by them greatly reduced. People should be taught that these lesions may in great part be prevented by the immediate disinfection of the sputum. Any consumptive who is well on the road of recovery may diminish his chances of regaining health by self-inoculation if he does not exercise the greatest care in destroying his sputum. And the fact that every consumptive may be a source of danger not only to himself but also to his associates if his sputum is not destroyed, should make

him doubly anxious for correct information on these points. With proper precaution victims of this disease may pursue their usual avocations without endangering others in the least, and for long periods of years they are often able to perform the ordinary duties of life with impunity.

The experience of several cities, notably New York and Philadelphia, shows that rooms occupied by consumptives are veritable centers of infection for the spread of tuberculosis, and maps employed for recording cases of consumption argue more forcibly than words for its infectious and communicable character. One of the most prominent characteristics of an infectious disease is that persons who come in contact with affected individuals fall victims to it. How closely consumption follows this law is beautifully demonstrated by a comparison of the diagrams of smallpox, diphtheria, typhoid fever, and scarlet fever with those of phthisis in the city of Philadelphia, for the grouping and localization is almost the same. Such being the case, no argument is necessary to show that all premises vacated by consumptives by reason of death or change of residence should be thoroughly renovated or disinfected before being again occupied. Moreover, I believe that in all hospitals, poorhouses, asylums and jails those persons affected with consumption should be separated as much as possible from the other inmates, as is now done in the insane asylums of our own State, and that in all such institutions, as well as in all factories, shops, and other buildings where people are accustomed to congregate in considerable numbers, rules for the proper care of sputum should be posted in prominent places, and that such buildings should be subjected to regular inspection by the sanitary authorities for the enforcement of such regulations.

Another important administrative measure for the control of tuberculosis is the early diagnosis of all cases, and to that end boards of health in many cities throughout the country are now making bacteriological examinations of all samples of sputum submitted to them.

And last but not of least importance as a prophylactic measure I would recommend the establishment of special hospitals for the management of indigent cases of phthisis, and these hospitals I think should be supported by the State. I believe that the time will come when every large community will have in its immediate vicinity a hospital for the care of its consumptive poor. I do not now refer to sanatoria for curative purposes, but to places of shelter for incurables, homes for advanced cases, which are often confined to rooms whose surroundings are hygienically bad and which are daily becoming worse by reason of the absence of those special precautions which are so necessary to prevent the spread of infection.

The State of Michigan presents a very good illustration of the benefits derived from the intelligent sanitary supervision of communicable diseases, and also of the influence of general hygienic measures upon the death-rate of consumption. There were no registrations at all of deaths in Michigan before 1867, and practically the returns do not begin to be useful before 1869 or 1870. For the period 1870-74 the death-rate from consumption in the State was 112.1 per 100,000 inhabitants. From that time there has been a pretty constant decline in the death-rate until 1896 when it reached 90.4 per 100,000, a reduction of 19.3%, and that, too, without that thorough *special* treatment as an

infectious disease which is herein indicated. A very interesting fact in this connection, and one which serves to emphasize the point I am endeavoring to make, is that more than one-third of this diminution in mortality has taken place since the year 1891, at which time the Michigan State Board of Health first issued its leaflet on consumption and began its well-known "campaign of education" against the disease. But when we turn to the other infectious diseases we find that the combined effect of general hygienic measures plus special efforts at restriction, has been to reduce their fatality 60% for the same period. Inasmuch, therefore, as we know that the specific infection of consumption can be more easily controlled than that of any other of the principal infectious diseases with which we have to deal, are we not warranted in believing that the utilizing of those special sanitary measures for the restriction of tuberculosis which are well known to sanitarians would produce a much greater reduction in the death-rate from tubercular disease in our State? Many of them have been in force in New York City for several years, and Dr. Biggs, pathologist and director of the bacteriological laboratories of New York, says that most beneficial effects have already resulted from them. Not only has there been a very material decline in the number of deaths from consumption, but there has also been a most gratifying increase of knowledge as to its nature among the poorest class of the population.

Meningeal Hemorrhage.—Wiemann (*Deutsche Zeitschrift f. Chirurgie*) reports 6 cases of meningeal hemorrhage, 3 of which recovered and 3 died. The cause of the lesion of the bloodvessels was the result of a severe injury. In 4 of the cases there was marked injury to the scalp. In those cases on which postmortem was obtained, the injury of the bloodvessel was found to have been caused by a sharp edge of bone, produced by the fracture, cutting directly into the vessel. In 2 cases the hematoma was found in the fronto-temporal region, in 2 cases in the temporoparietal region, in 1 case in the parietal, and in the remaining case the hematoma was diffuse in character. The clinical symptoms were very variable, and in only 2 cases was the typical picture of meningeal hemorrhage observed. The chief or main indication of extradural bleeding, that of an interval of freedom from all symptoms, was wanting in 5 cases. In a few cases the characteristic changes in pulse and respiration were noticed. The character of the pupil also varied greatly; sometimes they were dilated, sometimes strongly contracted, but generally reactionless. The convergence of the eye towards the injured side was noticed only in 1 case. In 4 cases a disturbance of motion was detected in those parts of the body corresponding to the cen-

ters pressed upon by the hematoma. In 3 of the patients the operation of opening the skull, for the purpose of removing the clotted blood and to check the hemorrhage was carried out. Operation of opening the skull consisted in all cases in turning down an osteoplastic flap with chisel and mallet. Wiemann lays great stress upon the advantages of such operation over simple trephining. The clot was generally removed with the finger or sharp spoon. The most important reason for removing the clot is to get rid of a soil on which bacteria grow readily, and thus protect the patient against infection. The most difficult part of operating with chisel is probably the forming of a beveled edge, which, when the flap is returned to its normal place, will afford a projection. [G.B.W.]

Radical Cure of Inguinal Hernia in the Female.

—Wm. B. Coley (*Yale Medical Journal*, December, 1901, Vol. VII, p. 204), is of the opinion that the treatment of inguinal hernia in the female has not received the attention it deserves. From a careful study of the literature of this subject and from personal experience he finds that the number of cases of inguinal hernia in the female exceeds the total number of femoral hernia in both sexes and forms 60% of all cases of rupture in women. He reports the results of operation in 134 personal cases. With regard to the technic of operation Coley believes that the excision of the sac is a matter of great importance. Of 7 cases in which the sac was not found, 4 relapsed within a few months, and 2 were not traced. The opinion of Kelly that the removal of the sac is of little importance he believes likely to do much harm. Transplantation of the round ligament, Coley believes is never indicated. The incision is made $\frac{1}{2}$ to $\frac{3}{4}$ of an inch above and parallel to Poupart's ligament. The aponeurosis of the external oblique is slit up over the internal ring and dissected back to the edge of the rectus on the inner side and sufficiently to expose Poupart's ligament on the outer side. The sac is sought high up just below the edge of the internal oblique muscle. It is thoroughly freed from the round ligament, transfixed and tied off with catgut. The wound is then closed in 3 layers, kangaroo tendon being used for the buried sutures, and catgut for the skin. The deep layer of sutures, 4 or 5 in number, are introduced from above downward, bringing the internal oblique and transversalis muscle over to Poupart's ligament. The round ligament is allowed to drop back into the lower angle of the wound; the aponeurosis is closed with continuous kangaroo-tendon sutures. The skin is closed without drainage, and the wound dressed with 10% iodoform gauze and moist bichlorid gauze 1:5000. Prior to December, 1898, when Coley began to use rubber gloves, he had 96% of primary wound healing. Since this date, in 150 cases of hernia he has had but one suppuration in which it was proved bacteriologically to have been due to imperfect sterilization of the skin. The question of the merits of absorbable and non-absorbable material for hernia operations is discussed at some length. At the Hospital for Ruptured and Crippled, Coley states that he and Bull have been using both catgut and kangaroo tendon for 10 years. Frequent bacteriologic examinations have always shown that the suture material is sterile, and experience has shown that the sutures remain unabsorbed sufficiently long to fulfil all the requirements for this operation. Cutting the external oblique muscle is considered not only unnecessary, but likely to weaken the canal, for the nerve-supply of the muscle fibers is divided laterally, depriving the mesial portion of its nerve-supply and when drawn down the direction of the muscle fiber is changed so that it does not work so advantageously as if parallelism with Poupart's ligament had been maintained. Since 1892, Coley has operated upon 134 cases of inguinal hernia in the female without a death. The ages of these patients have ranged between 40 and 70. Eighty patients were under 14 years of age. In 8, cases or 5.9%, suppuration occurred, though in every case it was slight and limited to stitch-hole infection, not prolonging the stay in the hospital. The average time which the patient was kept in bed has been 10 days, and they have been allowed to go home at the end of 2 weeks. A spica bandage is kept on for 2 weeks longer, at the end of which time support of all kinds is discontinued. All but 13 of the cases have been traced, and not a single relapse has been observed, though in 16 cases only from 6 months to a year has elapsed after the operation. [M.B.T.]

The Philadelphia Medical Journal

A Weekly Journal Owned and Published by The Philadelphia Medical Publishing Company and Conducted Exclusively in the Interests of the Medical Profession

JAMES HENDRIE LLOYD, A.M., M.D., *Editor-in-Chief*

Dr. Gould's Retirement.—The following resolution was adopted January 8, 1901, at the Stockholders' meeting of the Philadelphia Medical Publishing Company:

"With the beginning of the fourth year of the existence of the PHILADELPHIA MEDICAL JOURNAL, the Stockholders of the Philadelphia Medical Publishing Company desire to place on record their sense of deep appreciation of, and to extend their cordial thanks for, the energy and enterprise displayed by the late editor of the JOURNAL, Dr. George M. Gould, and the loyalty and fidelity of his collaborators, to which are due largely the phenomenal circulation and influence that have been attained in such a comparatively short time."

The following resolutions also were passed a few days before, by the Board of Trustees, pertaining to the same subject:

"WHEREAS, The term for which Dr. George M. Gould was elected editor of the PHILADELPHIA MEDICAL JOURNAL expires December 31, 1900; and,

"WHEREAS, The plans of the Board of Trustees provide for a change in the organization of the business and editorial departments for 1901;

"Be it Resolved, That the secretary notify Dr. Gould that his services as editor will not be required after December 31, 1900, and,

"Resolved, That the Board officially express to Dr. Gould its high appreciation of the eminent services which he has rendered the Company during the three years he has been editor of its JOURNAL; and its desire that his earnest labors in behalf of the medical profession may ever be fruitful in good results."

The Influenza.—The present epidemic of grip does not tend to support the opinions of those who have predicted that an immunity to this disease would gradually be established, and that influenza itself would die a natural death for want of material upon which to feed. On the contrary, the fact has been notable from the very first appearance, about ten years ago, of this prevailing infection, that the grip has had a tendency to attack the same victim repeatedly, and that it has slowly and surely become an endemic disease amongst us. This is certainly contrary to what we expect to see in an infectious disease, and to what we actually do see in most of the other so-called zymotic diseases. And yet that grip is an infectious disease, or the product of a microbe, there is no reason to doubt. That it is contagious, in the sense that as in any microbial disease the spores or the bacilli themselves can be passed from one person to another, is not to be doubted; and yet it is probably not so highly contagious as some observers contend. Certainly, with our present knowledge, it is not desirable that alarming statements to that effect should issue from the medical profession.

Where all persons are exposed to the same cause many may be affected without direct personal contagion.

With reference to the subject of immunity from grip, we wish we could chronicle some more encouraging facts. Turney (*Lancet*, Feb. 5, 1898) made a special investigation on the subject of relapses, and found in England that quite 10% of the cases relapse. How many persons have second, and even third and fourth attacks in succeeding years, we do not know. Turney thinks that if any immunity is conferred it is unimportant, and that a first attack even seems to predispose to a second. Many observers in America will confirm this statement. Gresswell claimed that healthy persons are more liable to be attacked than those who have been in bad health. With reference to the complications and sequelæ of grip, it is well to remember that many of these are probably due to secondary infection. Thus the pyogenic microbes may cause a purulent pleurisy, or the pneumococci may cause a pneumonia. For these and other infections the grip merely prepares the soil. The disturbances in the nervous system are probably due to toxins, although some of them closely simulate organic lesions. Thus a paralysis of the sixth nerve, occurring as an early symptom, was observed in a case in this city last year. In the present epidemic in Philadelphia grave complications of any kind are not so common as in the earlier years.

With reference to treatment, there seems to be nothing new, and nothing very effective. There is no specific for grip, and until we have a protective or a curative serum there probably will be none.

The Third Pan-American Medical Congress.—The fact that this approaching Congress is to assemble in Cuba gives it quite a unique importance. That island, which historically is one of the oldest communities in the new world, has only just recently joined in a full sense the American community of nations. Whatever may be Cuba's political position in the future, her geographical and commercial position will always make her an important if not a distinguished factor in the public life of this continent. In the medical and hygienic sense her existence on our very borders gives her a first-rate importance with her many unsolved problems of tropical diseases and tropical civic life. We in America are deeply interested (if even in a selfish

way) in some of these Cuban hygienic problems, and we are also desirous of seeing the island brought into closer relations, both commercial and professional, with our own country. It thus seems that the idea of holding the next Pan-American Congress in Cuba is a happy one. Moreover, the occasion offers a splendid excuse for some hardworked American physicians to take one of the most delightful winter trips imaginable. The round trip, including attendance at the Congress, and some sightseeing, can be taken in a comparatively short time. Personal acquaintance with Cuba as a winter resort will not be a bad thing for a doctor to have as part of his education.

The program offers an attractive collection of titles. The fact is noteworthy that most of the authors are from the large cities of the United States; in fact, to read the program, one would imagine that New York, Philadelphia, Chicago and Cincinnati constituted the real "Pan-America." When the owners of the familiar names printed on this program come together in Havana, they will probably find it difficult to realize that they are on a foreign soil. We are rather impressed with the limited rôle of some subjects for which Cuba stands in a special way, such as yellow fever; and we trust that the actual work of the Congress will bring out more discussion and more light on this subject than the program seems to promise.

Surgical Intervention in Perforative Cases of Typhoid Fever.—Dr. Osler's paper, which is presented in this number, brings up the question of operative procedure in perforation of the bowel in typhoid fever. It is asserted confidently that a certain percentage of the fatal cases from this complication can be saved by early operation. We are told that such patients bear the operation well, and that in the cases observed the ill-effects have been attributed to the operation itself. Dr. Osler's authority on such a point is important and reassuring. There are some considerations, however, that are not always taken into account. The post-operative effect of the surgical intervention and especially the effect of the anesthesia does not cease with the return to full consciousness and the passing off of the well-known symptoms of shock.

We have caused the patient weakened by the battle with the fever to exhaust still further his waning strength. In the truly terrific primary cardiac stimulation of the anesthetic can such an event fail but to be followed by its period of compensatory lowered vitality? Not perhaps showing itself by marked shock but a progressive asthenic decline. We have merely sounded a note of warning as to the effect of operation *per se* in the course of a progressive febrile affection such as typhoid.

We agree fully in the opinion of the value of operation in perforative cases, and would urge with Dr. Osler the necessity of careful personal observation of the

earliest symptoms of the complication. That even the most expert clinicians fail to detect perforation in all cases shows the great need of further knowledge upon the initial symptoms of its onset. Let us pay great heed to every detail, nor think no point of minutiae too slight to be carefully taken into consideration. The suggestion that typhoid cases be examined carefully upon the slightest occasion, not by an inexperienced interne, but by a trained clinical observer, should be taken to heart. No less valuable is the suggestion, that students receive constant bedside instruction in this disease and not depend upon textbook or lecture. This is a plea for progressive teaching which it should be our duty, as physicians and as humanitarians, to preach as gospel.

The Medico-Legal Aspects of the Case of Cadet Booz.—From the purely medical standpoint this now celebrated case is of interest from the fact that it has raised the very important question of the causation of tuberculosis under extraordinary circumstances. There seems to be no doubt that Cadet Booz died of pulmonary tuberculosis, two years after leaving the Academy. This disease, according to the allegations of his friends, was induced by certain maltreatment which he received in the process of "hazing" at West Point. The particular offence complained of was the administration of Tabasco sauce—a very hot and irritating condiment. A logical statement of the accusation, therefore, would seem to be, that the administration of an irritating condiment, such as is used quite commonly on the dining-table, can cause an injury to the larynx, and upon the seat of this injury tubercular infection can occur which leads eventually to generalized pulmonary tuberculosis. This, as we have said, is a medico-legal point of great importance, not only as it concerns the fair fame of West Point, but as it possibly might establish a precedent of importance in medico-legal practice. The Military Court of Inquiry, which has just finished its work, did not, it seems to us, take a very serious view of this medico-legal point, or attempt to throw much light upon it, but has contented itself with a mere statement that Cadet Booz did not come to his death as a result of hazing.

Primary tubercular laryngitis is, according to all authorities, an extremely rare disease. Morell Mackenzie says that he saw but three cases postmortem in which the larynx alone was involved, *i. e.*, in which there were no tubercular foci in the lungs. It is conceded, however, that such isolated cases may occur. The vast majority of cases of laryngeal tuberculosis are secondary to a lung lesion. The possibility of a wound or injury of the larynx acting as an exciting or predisposing cause of tubercular infection cannot be pointblank denied, but such a contingency is regarded as likewise highly improbable. Some cases, we believe, are recorded, but their significance is at least open to doubt. As tuber-

culosis is an infectious disease, it cannot exist, of course, without the action of its particular bacillus, but in a grave medico-legal case the proof would have to be overwhelming that the injury had been such as to predispose to an infection by the bacillus, and nothing like this was attempted in the inquiry into the case of Cadet Booz. It would likewise be necessary to prove that the laryngeal disease was primary, and not secondary to a lesion in the lungs. This case has created a great scandal in the public mind about West Point, and it is all the more desirable, therefore, that no injustice be done to either side by an inadequate sifting of the medico-legal evidence. Hazing, at its best, is foolish horse-play, but when it leads to physical injury and disease it is intolerable, and any accusation of the kind should be tested with all the recognized rules of evidence, as well as by the teachings of medical science.

Spinal Cocainization and Mental Shock.—The latest pronouncement on the subject of spinal cocainization comes from Dr. Maurice H. Richardson, of Boston (*Boston Med. and Surg. Jour.*, January 10), and is inspired by a visit he made last August to Tuffier's clinic in Paris. The value of Dr. Richardson's judgment on surgical subjects will be disputed by none, and his unusually good opportunity to witness this new method in a clinic where it is used so skillfully, gives his judgment all the more interest and importance. Dr. Richardson, in brief, saw two major abdominal operations performed on patients who were lying with almost imperceptible pulses, blanched faces, and perfectly conscious minds. One of these operations was for the removal of two ovarian cysts, and the other for a large renal tumor. The skill with which the operations were performed was brilliant and remarkable, and the impression made upon the minds of the group of American surgeons present was altogether favorable, so far as the operator and his technic were concerned; but the impression made on Dr. Richardson's mind by the ghastly and even alarming condition of the patients was distinctly unfavorable to this method of anesthesia. The condition, as described, was not unlike surgical shock. The pulse was almost imperceptible, but not greatly accelerated; the face was blanched, and the patient, perfectly conscious, said repeatedly that she felt no pain. How much of this condition was due to the cocain; and how much to the overwhelming mental impression, is uncertain, but we are strongly inclined to believe, after reading Dr. Richardson's graphic description, that the state of mental shock, caused by the patient's full consciousness of the horror of the whole surgical procedure, was the vitally important fact. What permanent, or even lingering effect, this shock may have upon a patient is, of course, as yet a mere speculative subject, and one which surgeons, who usually see little of their patients long after an operation, may not deem important; but we are glad that a

surgeon himself, like Dr. Richardson, has recognized this dreadful mental state, and has appreciated it fully and described it accurately. To our mind it furnishes one of the strongest arguments against spinal anesthesia, for we believe that few patients, and especially few women, are so constituted in their nerves that they can lie fully awake and see their abdomens opened and evacuated of tumors, without receiving a mental shock which may be most disastrous in its far-reaching effects.

Infantile Scurvy in the Island of Cuba.—Until very recently this disease had not been recognized in Cuba. In fact the subject had never been discussed there until Dr. J. L. Duenas, of Havana, contributed his most interesting article on the subject in a recent number of the *Archives of Pediatrics* (January, 1901). Dr. Duenas says that since 1894, when Northrup and Crandall read their paper on Infantile Scurvy before the New York Academy of Medicine, he had looked in vain for an instance of this disease in his practice until 1898, when he had the opportunity of seeing one case of the ordinary type, which promptly recovered under the usual treatment. In Duenas' opinion the severe forms of infantile scurvy are comparatively rare in Havana, especially considering the present condition of public health in that city. The point of special interest which he makes in his paper is a possible relationship in very young children between a severe type of infantile scurvy and a form of pernicious anemia. Such observations, so far as we know, have been very rarely made, and as Duenas' paper is founded upon a carefully observed case it is worthy of special comment.

The patient was a mulatto child 24 months old. After being weaned at 6 months the child was kept on a diet consisting largely of rice. This diet was badly borne and the patient suffered frequently from indigestion, diarrhea, and fever. The child did not walk until she was 16 months old. When Duenas first saw the patient there were great pallor and emaciation with poor physical development. There was no evidence of rickets nor of any other disease, but the left lower limb was swollen and painful. The borders of the gums were purplish, but neither spongy nor hemorrhagic. The stools were abnormal and fetid. Bleeding was very free from a pinprick made for the purpose of obtaining a specimen of the blood. On a diet of fresh cow's milk and the juice of an orange every day the scorbutic swelling of the leg rapidly disappeared and the child seemed to improve. But this improvement was not lasting. After a few weeks the child had become still more anemic with an earthy hue and a wrinkled skin. Petechia and ecchymotic spots were also seen on the skin of the trunk. An examination of the blood afforded a series of data of diagnostic importance. Laveran's plasmodia were not found, nor was there any agglutination of Eberth's bacillus. It is thus

seen that the diagnosis of malaria or typhoid fever could be laid aside. There was, however, an advanced poikilocytosis and a large number of macrocytes and microcytes, two very prominent characteristics of progressive pernicious anemia. There were found no nucleated red cells. The child failed progressively and died.

In discussing the significance of the case, Duenas calls attention to the fact that the etiological factors of scurvy, such as premature weaning and an excess of farinaceous diet (rice) were present. The clinical symptoms of scurvy were also well marked, and a rapid disappearance of these symptoms occurred under antiscorbutic treatment. On the other hand the diagnosis of what might be called a secondary pernicious anemia was plainly justified by the clinical symptoms and the microscopic examination of the blood. The unfavorable progression of the case after the first improvement in response to antiscorbutic treatment, is also in favor of the diagnosis of a grave degenerative affection of the blood. The exact relationship of these two conditions is of course difficult to determine in an isolated case. It is well known that symptoms simulating pernicious anemia sometimes occur when the system has been much depleted. They have been seen, for instance, in cases of intestinal parasites. We are not familiar, however, with any instance, certainly with any marked instance, of the disease occurring in early childhood following upon an infantile scorbutus which had already begun to mend under appropriate treatment.

The Significance of Right-sided Pelvic Pain.—

Fully 65%, and probably more, of the pelvic pains of womankind are experienced upon the left side. An explanation of this clinical phenomenon is afforded by an anatomic study of the parts. For the same reason that varicocele of the left scrotum is much more frequently encountered than a similar condition on the right side, left ovarian and tubal disease of intrinsic origin is much more common than a corresponding inflammatory condition on the right side. As is well known, the left ovarian vein empties into the left renal vein at right angles and without the protection of a valve, and this vessel in its turn communicates with the vena cava; while on the other hand the right ovarian vein empties directly into the ascending vena cava, and is furnished with a valve at the point of junction which opens upwards into the cava, whereby regurgitation is prevented. On the left side, therefore, stasis, the inevitable result of feeble suction from a comparatively slowly moving blood-current, aided by the action of gravity exerted through the more or less perpendicularly running vessel, is of frequent occurrence, and there follow of necessity a primary hyperemia and a secondary chronic or subacute inflammation of the tissues of the corresponding broad ligament with prolapsus or descensus ovarii, and pain and all the other sequences of adnexal disease.

There may, however, and in a certain proportion of the cases encountered in a large private or dispensary practice there will, be found actual inflammatory changes with or without exudate in the right broad ligament, while cirrhosis of the ovaries—the disease of sterile women—will occur just as surely upon the right as upon the left side, and dermoid cysts and other cystic formations show no predilection for either side.

On the other hand, however, a curious clinical fact is the more frequent occurrence of tubal pregnancy on the right side. Bland Sutton has recently announced that from his studies, both clinical and postmortem, he has come to the conclusion that tubal gestation is much more prone to occur in a healthy than in a diseased tube. Admitting the truth of this statement, which it must be recognized is at direct variance with the teachings of the accepted textbooks of the day, it is not difficult to demonstrate a relationship between these two clinical facts. If left tubal and ovarian disease is more common than right disease of the adnexa, and if extrauterine pregnancy is more commonly encountered on the right side—granted that Bland Sutton's statement is true—then the frequency of right tubal pregnancy is directly dependent upon the greater frequency of a healthy tube upon that than upon the left side. Now, the most striking clinical manifestation of tubal gestation is pain, occurring in sharp paroxysms at irregular intervals, the pain being located in the right ovarian center a little below McBurney's point. With this clinical phenomenon associated with the early symptoms of normal gestation, a careful pelvic exploration will reveal the adventitious and exceedingly tender growth in close proximity to the uterine body, and the diagnosis may then be made before rupture has occurred and an abdominal section performed at once.

A pathological condition which not infrequently closely simulates the foregoing is appendicitis. The gynecologist, too often improperly confining himself to the pathology of the pelvic viscera to the total exclusion of other affections of the abdomen, is very apt to entirely overlook the occurrence of this disease in the woman, and to refer her symptom of pain to some obscure pelvic condition. The realm of the gynecologist, however, is the abdomen just as truly as the pelvis, nor should it be limited to the abdominal cavity, but should extend to the mammary glands also. Hence, attacks of pain in the right inguinal region should suggest to him, as to any other surgeon, the possibility of the presence of an appendicitis, and not infrequently a close investigation of the appendix may elucidate an otherwise obscure case, and offer to the patient chances of recovery that might be forfeited by neglect of this important procedure.

Finally, every gynecologist has noticed the occasional occurrence of a referred pain in the right ovarian region, in cases in which a most careful pelvic explora-

tion reveals a normal condition of that side of the pelvis with, however, a considerable degree of morbidity on the opposite side. This is a curious phenomenon, and is a direct outcome of the intimate anastomoses that exist between the pelvic nerve plexuses, and is a congener of the other, and probably better known, referred gynecologic pains, namely, those extending down the inner surface of the thigh, radiating to the small of the back, transmitted to the mammae, or to the shoulder-blade, and referred to the top of the head, the so-called *clarus hystericus*.

In these cases, removal of the offending organ on the left side will generally, but not positively, cure the reflex pain.

To resume, then, pain in the right ovarian region, or its immediate vicinity, may indicate one or the other of the following conditions: First, a direct involvement of the organs—ovary, tube, broad ligament, or pampiniform plexus—of that side, as demonstrated by macroscopic or microscopic lesions; secondly, right tubal or broad ligament pregnancy; thirdly, appendicitis; and fourthly, simply a transference of a symptom from a diseased appendage on the opposite side without any appreciable right-sided disease.

Erratum.—A typographical error in the fifth line of the first column of page 49 in our last issue demands correction. The line should read: "present with its point of *selection* the respiratory," etc.

Correspondence.

A HAT-PIN IN THE MALE URETHRA.

By P. J. KRESS, M.D.,

of Allentown, Pa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

UNDER correspondence in your JOURNAL, Vol. VI, No. 24 Dr. Thomas M. Paul, of Hazleton, Pa., gives report of a hat pin, six inches long, extracted from the male urethra, also there being no record of a similar case.

In 1895, during my term of service as assistant surgeon at the State Hospital, where the doctor is at present, we had a similar case.

A man, aged about 60 years, used a hat-pin about five inches in length, if I remember correctly, in his urethra to produce sexual excitement. The head of the pin slipped into the bladder and drew the end of shaft within the meatus about one inch. In attempting to get a hold of the pin he pressed the point in the lower wall of the penis, causing severe hemorrhage.

When brought to the hospital it was impossible to get the pin through the meatus, and the shaft being run into the tissue obliquely the opening was enlarged by cutting along the shaft from the external side, and the pin then drawn out. Dressings were applied and the wound healed nicely.

This case being much like the doctor's, and occurring in the same institution, gives me reason for reporting it.

TUBERCULOSIS AMONG RUSSIAN JEWS.

By A. L. BENEDICT, M.D.

of Buffalo, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I HAVE read with interest Dr. Maurice Fishberg's letter criticising an article by Miss A. Dutcher in regard to the frequency of tuberculosis among the Russian Jews. His remarks as to ethnologic classification are certainly correct, yet it is sometimes practically impossible to avoid classifications that are ludicrous if interpreted in the strict scientific sense. For instance, pregnancy, which is certainly a physiologic state, must often be treated statistically as a disease. In 1890-91, I made a considerable number of life-insurance examinations which included the work of one or two agents among "Russ-Pole-Jews." Almost all of the applicants were rejected as under size and having insufficient chest expansion. A large proportion—I should say fully half—also presented the physical signs of incipient tuberculosis. Most of the applicants were workers in sweat shops, and they seemed surprised not to be considered in good health. Since then, I have had some little clinical experience confirming the idea that tuberculosis is much more frequent among these Jews than among the average of the population and, certainly among the Jews of other nationality. Personally, on account of some study in genealogy and heredity, I am inclined to think that the importance of heredity in the etiology of disease has been much overrated. The fact that the Russian Jews are prone to tuberculosis has nothing to do with their being Jews, with their having lived in Poland, with their forced adoption by the Russians. For several generations, at least, they have been persecuted to such a degree that they have been compelled to live in unhygienic surroundings and to subsist on inadequate food. Since coming to America, those to whom I refer and, presumably, those who fell under Miss Dutcher's observation, have been occupied mostly in sweat shops or, at any rate, have been herded together in too crowded living rooms. Manifestly, the same causes that tend to render these persons tubercular, also make them a source of danger to the community at large.

Dr. Fishberg's statistics seem to be incontrovertible, except by the general scepticism which one may feel regarding all statistics gathered in the ordinary routine of Boards of Health. But, it should be noted that his minimum death-rate from tuberculosis is credited to "Russia and Poland"—a very different thing from the class under discussion. We have in Buffalo a considerable number of Poles. No recent statistics are at hand and they breed so rapidly that the 1890 statistics are of no use, even if we disregarded immigration, which has also been considerable. Probably we have not less than 30,000, nearly 8% of the total population. In contrast with the "Russ-Pole-Jews," they are mainly outdoor laborers, especially in market gardens in the suburbs and, so far as possible, each family secures a separate cottage and a little plot of ground. Naturally enough, they are not prone to tuberculosis and, if we include the scanty population of highly tubercular Russ-Pole-Jews in this great mass of Slavs, where they do not belong either ethnically or clinically, we must expect an obscuring of fact by figures.

Influenza.—It is estimated that there are 70,000 Philadelphians suffering from influenza.

Special Article.

AN ABSTRACT OF THE REPORT UPON THE EPIDEMIC OF PEST IN JAPAN FROM NOVEMBER, 1899, TO JANUARY, 1900.

By PROFESSOR S. KITASATO,

Director of the Imperial Institute for Infectious Diseases,

AND

DRS. T. TAKAKI, K. SHIGO, and G. MORIYA.

Translated, with permission of the Minister of the Interior,

By MAURICE OSTHEIMER, M.D.

THE epidemic of pest appeared in Japan early in November, 1899. A commission for directing the prophylactic measures necessary to bring the epidemic under control, and for scientific research, was sent to Kobe and Osaka at once by the Japanese government. Professor Kitasato, Director of the Imperial Institute; Dr. Takaki, Councillor in the Ministry of the Interior; and Drs. Shiga and Moriya, Instructors in the Institute, were named to form this commission. They succeeded in extinguishing the plague by the middle of January, 1900. The number of patients in the two cities was 64. They were:

	Died.	Recovered.	Total.
Bubonic plague.....	39	4	43
Pest-pneumonia	13	0	13
Pest-carbuncle	3	2	5
Septicemia	3	0	3
Total	58	6	64

Of these, 35 were treated in hospitals, 29 of whom died. The other 29 died at home.

In Kobe, a city of 230,000 inhabitants, the pest arose among laborers engaged with ship's refuse. Thus 7 of the 25 cases found in Kobe are traced directly to a ship which had arrived from Bombay and Hong Kong in October; 3 others had been buried with ship's refuse; in 6 cases dead rats containing pest-bacilli were found in the houses; and in 3 cases infection followed from contact with pest-patients. In the remaining 6 cases the mode of infection is not known.

In Osaka, in size the second city of Japan, with 750,000 inhabitants, the pest is supposed to have entered through infected wadding, though there seems some cause for suspecting that the wadding had been infected by rats. The first four cases bear direct relation to this wadding, in which pest-bacilli were found by Dr. Iwai, Director of the Osaka Municipal Hospital for Infectious Diseases. The early cases, like those in Kobe, were bubonic in character. Toward the middle of December, however, the epidemic grew more malignant, several cases of pest-pneumonia occurring by direct infection.

In the western part of Osaka lies a small island, *Shikanishima*, on which there is a cotton-spinning factory, *kanekinsuishoku kaisha*, where over 1,600 women and hundreds of men are employed. In one room of this factory, in which 63 women and 10 men worked, was a girl named M. Adachi. She was taken sick December 19, 1899, with symptoms of pneumonia, and died the 21st. Both the attending physician and the medical inspector made the diagnosis of croupous pneumonia; the corpse was therefore burned. Two days after her death her parents became ill with exactly the same symptoms. Careful examinations were made and pest-bacilli found in the sputum. As it was primary pest-pneumonia, in which the danger of infection is very great, even stronger precautions were taken. The patients were conveyed to the Municipal Hospital for Epidemic Diseases; those who had been exposed were taken to the Municipal Isolation Pavilions; and their homes were at once disinfected.

On December 25, in the room in which M. Adachi had worked, a woman developed a pest-bubo. A systematic disinfection of the entire factory followed. The men and women were isolated and examined daily by physicians. Among those isolated, four cases of pest developed, two the next day, one 3 days later, and one after 6 days. These all had bubonic

pest, in spite of the fact that the bacilli originated in M. Adachi, who had pest-pneumonia. Though the other Adachis were isolated, 6 deaths occurred in the family, the only one spared by the disease being a four-year-old child.

But the power of the disease had not yet reached its end. The physician, K. Wakabayashi, and the medical inspector S. Baba, who had examined and treated M. Adachi, her parents, and U. Adachi, also developed primary pest-pneumonia December 30. The third physician, T. Yamanaka, a friend of Wakabayashi's, whom he had treated before his transfer to the hospital, became ill January 4, 1900. Besides these, Mrs. Wakabayashi, and Mrs. Baba were taken sick January 3; Wakabayashi's jinrikisha man, January 5th; Mrs. Yamanaka, the 10th; and Yamanaka's mother the 11th. All suffered from primary pest-pneumonia; in all the disease was fatal.

Looking back now, the course of the infection is easily traced, beginning with the girl, M. Adachi, whose disease, diagnosed croupous pneumonia, was true pest-pneumonia. As she was a working-girl and lived in poorer circumstances, she kept at her work, though she did not feel well. As she had pneumonia, she coughed and probably also expectorated. In this way the pest-bacilli reached the floor of the work-room. Thus it is clear how two men and three women, working in the same room, contracted glandular pest. The infection probably did not come direct from the lungs, as M. Adachi worked facing the wall. That these people run about without sufficient foot covering helps to confirm this. That direct infection can follow in the family, from the patient's coughing, or from attentions to the patient, is beyond doubt. Among the physicians the conditions were the same.

It is well known that rats are very susceptible to pest-bacilli, and therefore well adapted to propagate the germs of the disease. On this account pains were taken to exterminate them if possible, the municipal authorities paying 5 sen (2½ cents) for every rat delivered to them dead or alive. In Kobe the total number of rats bought reached 20,000; in Osaka, 15,000. Even more rats were caught which did not come to the knowledge of the authorities, having been destroyed by private individuals. About one-fifth of the dead rats found in Kobe contained pest-bacilli; in Osaka only one-tenth.

In the main custom-house at Kobe pest-rats were found on November 21, 1899, and 12 days afterward, a schoolboy who lived 400 or 500 meters distant became ill. Upon searching, several pest-rats were found in the dwellings between the custom-house and the patient's home. The custom-house lies close to the sea, and his home is further inland, which confirms the supposition that the disease in the rats spread gradually up from the sea. Pest-rats were also found in the eastern custom-house and on the third landing stage in Kobe, whence it seems most probable that the rats came from ships. Pest-rats were also found in Gifu, where there were no cases of pest, which adds evidence to prove that the rats brought the pest-bacilli into Japan.

Whenever pest-rats were found near the house of a pest-patient, the bacilli were most probably spread by the rats. In 16 cases pest-rats were found in or near houses where cases of pest occurred. That pest-rats were found in dwellings far distant from the pest neighborhood, brings clearly to the front how closely the epidemic in the rats and in man were related. The district in which pest-rats were found is much larger than that in which cases of pest existed, though the most pest rats were seen where the epidemic raged most fiercely. While the relation of the single cases to the dead rats cannot be fully shown, we can surely believe that the rats first became ill, and then the epidemic broke out among men. That probably occurred because the rats had more opportunity to come in contact with infected objects than men.

From clinical investigations these conclusions were drawn: The number of males affected was twice that of the females; people from 10 to 40 years of age seemed most susceptible to the disease; the majority of patients were servants, laborers, and boatmen; the period of incubation lasted 3 to 4 days, though it reached 7 to 10 days in some cases. While the onset is generally sudden with a chill, it was in a few cases preceded by prodromal symptoms; in 19 cases, constitutional symptoms occurred before the buboes, while in 7 cases they appeared simultaneously. Petechial eruptions were infrequent, and true roseola was seen in 3 cases.

Carbuncles occurred upon the trunk in 5 cases, not once upon the extremities, as is commonly the case; which was probably due to the peculiarities of Japanese costume and the customs of Japanese life. In all cases the carbuncles were primary, and pest-bacilli were found. They lasted on an average 11 days; while the other forms of the disease rarely existed over 8 days. Total extirpation is advised as the only treatment. Femoral and inguinal buboes occurred in 75 of the bubonic cases, in all of which were pest-bacilli. The main treatment employed was total extirpation of the buboes. Four out of 13 cases thus treated recovered, all of which were inguinal or femoral. In Osaka, during the second half of the epidemic, 13 fatal cases of pest pneumonia occurred, conveyed by contact one to the other. Not the slightest difference in the clinical symptoms in primary and secondary pneumonia was found; only in the latter bloody sputum is rare, as the patient dies too soon. Treatment of pest-pneumonia by the "Yersin" serum proved of no avail. Six cases of mixed infection were observed. Beside the pest-bacilli, septicemic bacilli like those of chicken-cholera, staining deeply by Gram's method, staphylococci, and streptococci were seen. A positive diagnosis can be made by bacteriologic examination only. On the other hand, a negative result from bacteriologic examination is of no certain significance, since during the onset of the disease the few bacilli there may easily escape the field of the microscope; in pest-pneumonia, especially at the outset, frequent examinations must be made.

For prophylaxis the "Haffkine" serum, the "Yersin" serum, and a new serum made by Dr. Shiga's method were tried. The "Haffkine" serum was used many times successfully, the only case of pest developing after its use being in a woman who was probably infected before being injected.

But Dr. K. Shiga had, at the time of the epidemic of dysentery, tried protective inoculation against that disease. According to his method the vaccine was made thus: the dysentery cultures were ground up in an agate mortar, normal salt-solution added, and then heated to 60° C. for 20 minutes. As the substance of the dysentery-bacilli is absorbed with difficulty and causes marked infiltration about the site of injection, a quantity of immunizing serum was added, equal to that of the vaccine made. In this manner it is absorbed with the least possible reaction, and protection follows without great discomfort to the patient. After a few days a stronger injection follows; the vaccine is inoculated without the immunizing serum, as the substance of the bacteria will now be easily absorbed.

This method was tried with the pest. The vaccine was made as follows: All the colonies (5 oese full) are scraped from slant agar cultures which have been kept 3 days at 30° C., ground up in a mortar, and normal salt-solution added, enough to make 1 ccm. of vaccine contain 1 oese of bacilli. The mixture is then heated at 60° C. for 30 minutes, carbolic acid added up to 0.5%, and allowed to stand 24 hours. The dose of the vaccine is the following, first injection:

Vaccine..... } of each—0.6 to 1.0 ccm.
Immunizing serum..... }

A few days later, after the reaction had disappeared, the second injection follows:

Vaccine..... 0.6 to 1.0 ccm.

These inoculations were given to 47 persons, not one of whom caught the pest. The reaction to the injections was very slight, and very well borne. The symptoms of the reaction are: (1) Slight pain, or tension feeling over the seat of the injection; (2) slight tenderness and redness with elevation of temperature (99.5° F.); or more rarely (3) slight swelling of the seat of the injection, mild fever (100.4° F.), slight headache, with chills, etc. In epidemics of pest, larger doses of this vaccine, which can now be prepared in large quantities in the Institute for Infectious Diseases, may be given.

Of the case histories, the following is the most interesting: From November 15 until December 4, Ch. Yase, a police servant, 21 years old, was on duty during the quarantine of the pesthouses. On the 6th he noticed in the right hypochondrium a reddish swelling which itched, about the size of a millet seed. His temperature was 101.8° F. The next day the swelling in the abdomen increased rapidly, becoming dark red and very painful. As he always feared pest infec-

tion, he kept feeling in the groin for buboes. That day for the first time he found a slightly sensitive spot in the middle of the inguinal region. The day following, the center of the abdominal swelling was dark brown, the swelling itself being as large as a saucer and very painful. In the most sensitive part of the groin a small bubo was palpable. The swelling pointed the day after, discharging a yellow purulent fluid. Numerous blisters appeared upon the swollen, infiltrated tissue surrounding, and a deep redness spread to the groins, so that the whole condition looked almost like erysipelas. Pest-bacilli were found in fluid withdrawn by exploratory puncture, and the patient was brought to the hospital. On admission, a carbuncle was found upon his abdomen, on the right side below the umbilicus, the infiltration reaching up to the umbilicus, down to Poupart's ligament, and across the linea alba. The head of the swelling was as large as a coin, depressed, and covered with a dirty brown crust. The right inguinal glands were much swollen. That afternoon crucial incisions were made, the infiltrated part of the carbuncle scraped out and the inguinal glands removed. Two days later, as the tissue between the carbuncle and the bubo was infiltrated and very sensitive, it was removed. The next day the left inguinal glands, which were somewhat swollen and painful, were also removed. The edges of the wounds upon the abdomen were still infiltrated, so that that tissue was cut out the day following. Twenty-four hours later a gland in his neck had become enlarged and tender and it was also removed. From this time on he slowly improved, and was discharged in excellent condition 6 weeks later.

To combat the epidemic, Japan first of all ordered that the law regulating the quarantine against ships from foreign harbors or from Formosa be more strictly enforced than before. Next the Minister of the Interior prohibited the introduction of rags, old wadding, old clothes, old bits of paper, old leather or skins, and old feathers from all harbors of India and China; from Hong-Kong and Formosa especially. Old carpets and old hemp-sacks were soon added to the list. All such material introduced before the issue of the above order was to remain where it was. Refuse from ships which came from infected ports must be burned, or thrown into the sea at a distance from land of no less than 12 kilometers. The length of observation for a ship infected with pest was increased from 7 to 10 days, and the isolation of those open to suspected pest-infection was also increased to 10 days.

As rats were considered pest-bearing and pest-spreading factors, the Government ordered them caught all over Japan. All dead rats were examined bacteriologically, and whenever pest-bacilli were seen, the houses in which the rats were found were disinfected. Comprehensive cleansing was undertaken in all parts of Japan, and in those cities in which the population is thickly crowded together, and trade very active, (as Tokio and Yokohama) medical inspection of laborers' quarters was established, in order to discover each case of pest just as soon as it appeared. When a suspicious case came to the knowledge of the authorities, a medical expert was sent to confirm the diagnosis. If the case was one of true pest, or strongly suspicious of pest, the patient was taken to the Municipal Hospital. In order to discover concealed cases of pest, medical inspection was established. In Kobe 229 physicians, in Osaka 374 physicians were engaged, each physician being given a policeman. Both visited their district daily, to register names and to examine cases. The physicians were ordered to specify in the death certificates when the patient became ill, when he was first examined, and when he died. In all cases of death from acute disease, an autopsy was held by pest experts.

The disinfection was left in the hands of the police. Dirty linen, clothes, bed-clothing, etc., were disinfected by steam; for furniture, floors, walls, columns, ceilings, and the spaces between the ceilings, and the space between the ceilings and the floor, or roof above, 5% carbolic acid was used. For the disinfection of cellars, kitchens, sinks, and water-closets, slaked lime or chlorid of lime was employed. Infected articles of little value, such as old clothes, mattresses, wooden shoes, etc., were burned.

Hospital-Ship Maine Reaches England.—The American hospital-ship *Maine* has arrived at Southampton, with invalids from China.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. Bushrod W. James was elected president of the Pennsylvania Fish Protective Association.

New Laboratory.—Plans are being prepared for a new medical laboratory for the University of Pennsylvania.

Dr. Arthur Remington has been elected to fill the position on the obstetrical staff of the Maternity Hospital, rendered vacant by the resignation of Dr. W. Constantine Gocdell.

Grip Epidemic at Princeton.—An epidemic of grip has spread with alarming rapidity through the University the past few days. There are 18 cases now in the University Hospital.

Huntingdon County Medical Society.—At the first regular meeting held January 8, the following officers were elected: President, Dr. Ella M. Gerlach; vice-president, Dr. Bruce P. Steel; secretary, Dr. A. B. Brumbaugh; treasurer, Dr. G. G. Harman.

Physician Falls from Window Dead.—Dr. James Boyd McKelvy, one of the most prominent physicians and residents of Bloomsburg, 76 years of age, died January 14. He was a graduate of Williams College and University of Pennsylvania Medical School.

The Mayor of Elizabeth Dead.—Dr. William A. Mack was found dead in bed at his home on January 14. Dr. Mack was born in Glen Gardner, N. J., 44 years ago. He began the study of medicine with Dr. Thomas L. Hough. He was a graduate of Bellevue Medical College, a member of the Union County Medical Society, and the Clinical Society of the Elizabeth General Hospital.

Resignation of Dr. J. W. Croskey.—At the meeting of the Board of Directors of City Trusts on January 10, the resignation of Dr. John Welsh Croskey as surgeon to Wills Eye Hospital was accepted, to take effect January 1 last, and on the recommendation of the committee of the hospital, Dr. McCluney Radcliffe was appointed to the vacancy. Dr. Radcliffe has been connected with the hospital for the past 17 years as assistant to Dr. George C. Harlan.

Annual Meeting of Delaware County Medical Society.—The annual meeting of the Delaware County Medical Society was held in Chester, January 10. The election of officers resulted as follows: President, Dr. George D. Cross, Chester; vice-president, Dr. Partridge, Ridley Park; secretary, Dr. Linneas Fussell, Media; treasurer, Dr. D. W. Jefferis, Chester; reporter, Dr. M. A. Neufeld, Chester; librarian, Dr. Trimble, Lima; censors, Drs. D. W. Jefferis, Fronefield and Hammond.

Germantown Hospital.—At the annual meeting of the contributors to the Germantown Dispensary and Hospital, held at the hospital building East Penn Street, Tuesday afternoon, the report for 1900 was read, showing that 1,080 patients were treated in the hospital proper during the year, an increase of 107, whilst in the dispensary there were treated 11,967. The following officers were elected: President, Elliston P. Morris; secretary, Thomas B. Homer; treasurer, William H. Haines. Managers, Elliston P. Morris, William H. Haines, Frank J. Firth, Francis Stokes, Reed A. Williams, Jr.; Alexander W. Wister, Jr.; William H. Scott, Thomas B. Homer, Morton Downs, M.D.; Thomas H. Shoemaker, Henry L. Davis, N. Penrose Allen, Edward H. Hance, George W. Woodward, M.D.; James Mapes Dodge.

Pathological Society.—At the meeting of January 10 DR. JOSEPH MCFARLAND exhibited: (1) An epithelioma of the mouth and skin of a white catfish, and (2) A case of thrombosis of all four chambers of the heart. The patient from whom the latter specimen was taken had not been very ill and the diagnosis of tuberculosis had been made. With the exception of the thrombi, a hemorrhagic infarct in one lung was the only lesion found. Drs. IDA E. RICHARDSON (by invitation) and J. D. STEELE showed

an Hourglass-contraction of the stomach. The patient died at the age of 38, having had gastric pain and hemorrhages more or less frequently since the age of 15. The contraction was very marked, being near the middle of the stomach and at a point where strong adhesions bound it to the pancreas and liver. Drs. F. X. DERCUM and W. G. SPILLER presented a paper on **Nerve fibers in the pia of the cord as a sign of regeneration of the cord.** This rare condition of nerve fibers in the pia was found in a case of adiposis dolorosa. The fibers were more numerous over the posterior columns of the cord and were confined to the lumbar and dorsal regions. The knee-jerks were not abolished and there was no degeneration of the posterior roots. Dr. L. NAPOLEON BOSTON read a paper on **Cultivation of the aspergillus in urine,** and showed specimens by the chromoscope. Drs. M. P. RAVENEL and D. J. MCCARTHY presented a paper on the **Rapid diagnosis of rabies.** The claims of Babes and Van Gehuchten were reviewed and the results of experiments at the University of Pennsylvania given. Drs. Ravenel and McCarthy have studied 28 cases of rabies in animals. These included 11 dogs, 1 cow, 1 horse, and 15 produced cases in rabbits. One case in a human being, a girl of 8 years, was also studied. In the animals 10 positive results were obtained from the plexiform ganglia. In 19 of 21 cases the rabic tubercles of Babes were found in the bulb. The claims of Van Gehuchten with regard to street virus are confirmed, the conclusion being that the changes in the bulb and ganglia, together with the clinical history, afford a rapid and certain evidence of the existence of rabies. Dr. W. M. L. CORLIN read a paper on **Branchial cysts.** The literature of the subject was carefully reviewed and a case reported.

Vital Statistics of Philadelphia for the week ended January 12, 1901:

Total mortality	487	CASES	DEATHS.
Induration of appendix 2, bladder 2, brain 16, bronchi 8, kidneys 21, lungs 53, peritoneum 6, pleura 1, stomach and bowels 14, spine 1			124
Inanition 10, marasmus 9, debility 3			22
Tuberculosis of lungs			52
Apoplexy 10, paralysis 10			20
Heart—disease of 43, fatty degeneration of 1, neuralgia of 1			45
Uremia 14, diabetes 3, Bright's disease 7			24
Cancer			12
Carcinoma of breast 3, stomach 3, uterus 4, face 1, leg 1, rectum 1, throat 2			15
Convulsions			15
Diphtheria	109		21
Brain—softening of 3, congestion of 5			8
Typhoid fever	111		—
Old age			18
Burns and scalds			8
Dysentery			4
Suicide			1
Cirrhosis of liver			2
Alcoholism			1
Cyanosis			2
Scarlet fever	71		6
Hernia			2
Access of the kidney 1, aneurysm of the aorta 1, asthma 1, anemia 1, congestion of the lungs 7, puerperal convulsions 2, meningitis 1, pleurisy 1, heart disease of the brain 3, of the liver 3, spine 2, drowned 1, dropsy of the abdomen 1, heart 2, chest 1, of the brain 1, erysipelas 1, goiter 1, hemorrhage of the lungs 2, homicide 2, influenza 5, intestinal obstruction 1, poisoning by strychnin 1, sarcoma 1, septicemia 3, smallpox 1, syphilis 1, tetanus 1, ulceration of the stomach 3, unknown coroner case 1, whooping cough 3, suffocation 1			62

New Lay Board of Trustees for Medico-Chirurgical College.—At a meeting held by the Board of Trustees of the Medico-Chirurgical College and Hospital, January 15, a change was made in the management of these institutions. The old board, consisting of Drs. John V. Shoemaker, James M. Anders, Ernest Laplace, W. Easterly Ashton, L. Webster Fox, William E. Hughes, William L. Rodman, Isaac Ott, Henry Fisher, W. F. Haehulen, George M. Boyd, W. C. Hollopeter, Samuel Disston, Esq., and William King, Esq., resigned after electing a new Board of Trustees. Under the management of the board just resigned the Medico-Chirurgical College and Hospital in the last 20 years (the first course

of lectures was given in 1881) has grown in importance until today it ranks as one of the three great medical institutions of this city. Six hundred students are in attendance during the present semester. There is a department of Medicine, Dentistry and Pharmacy, well attended by students from all parts of the United States and colonies. The selection of a lay board is a forward step in the still further progress of the college and will relieve the professors who have hitherto acted as trustees and managers of the college and hospital. The increased size of the classes and the broad policy adopted in teaching demanded all the time of the various instructors, so that it was necessary to hand over the business administration to a lay board, who will now be conducted by Judge Paxson and the new members just elected, and the Medico-Chirurgical College and Hospital will continue to progress in the future as it has in the past. The following gentlemen comprise the newly elected board: Hon. Edward M. Paxson, ex-Chief Justice, president; Hon. James P. Sterrett, ex-Chief Justice; Hon. A. M. Beitler, Judge of Court of Common Pleas; Hon. J. A. Logan, general solicitor Pennsylvania Railroad Company; Pemberton S. Hutchinson, Esq., president Philadelphia Saving Fund; Joseph L. Caven, Esq., president Real Estate Title Company; Henry D. Paxson, Esq., attorney-at-law; David Milne, Esq., manufacturer; W. Howard Pancoast, Esq., banker; Theodore L. Voorhees, first vice-president Philadelphia and Reading Company; George A. Hubn, Esq., banker and broker; John A. Grady, attorney-at-law; William King, Esq., honorary trustee; D. T. Pratt, Esq., honorary trustee.

NEW YORK.

The Manhattan Dermatological Society, of New York City, has been organized with the following list of officers: President, Dr. William S. Gottheil; vice-president, Dr. Ludwig Weiss; secretary, Dr. Jacob Sobel.

Prospective Medical Legislation.—Among the numerous bills relating to medicine that have been introduced into the State Legislature, the most important are the ones regulating midwifery, the protection of the physicians and surgeons from blackmail and unjust malpractice suits, and the eligibility of physicians to hold the office of the president of the Board of Health.

The Manhattan Dermatological Society.—The second regular meeting was held at the residence of Dr. L. Weiss, No. 77 East Ninety-first Street, with Dr. Wm. S. Gottheil in the chair. Dr. E. L. COCKS presented a case of **Lichen planus on a syphilitic base**. Dr. R. ABRAHAMS showed two cases of **ichthyosis in children** of 3 and 5 years of age respectively. Dr. J. SOBEL presented a case of **pediculosis pubis** showing to a marked degree the maculae, ceruleae, or hemorrhagic macules due to the burrowing of the crab louse. Dr. GOTTHEIL showed an **extensive lupus erythematosus of the face** and a **xanthema of the scalp**. A case of **hereditary syphilis** with lesions of the tongue and lips was also demonstrated by Dr. Gottheil. Dr. B. F. OCHS presented a severe case of **eczema rubrum** which had resisted all methods of treatment. Dr. WEISS presented a patient with **scrofuloderma of the cheek**, and a case for diagnosis. The latter was either a lymphangioma tuberosa multiplex, or multiple subcutaneous syphilomata, or gummata. A pathologic examination of one of the excised nodules by Joseph, of Berlin, showed nothing but **granulation tissue**. Aortic syphilitic treatment did not effect a permanent cure. Dr. R. ABRAHAMS showed a case of **tuberculosis cutis**, and Dr. SOBEL a **perforation of the hard palate**, due to a neglected gumma—an obturator afforded great relief. Dr. GOTTHEIL showed photographs of a case of **chromophytosis of the face** in a colored boy, the patches simulating leucoderma, and of **pityriasis versicolor of the palms**. The latter case, a rather unique one, was reported last year. Dr. SOBEL demonstrated the **mechanism and use of Allen's comedo extractor**. Dr. GOTTHEIL presented a case of **dermatitis herpetiformis** in a boy of 12, which had improved rapidly under the use of Fowler's solution.

New York Neurological Society.—Stated meeting held January 1, 1901. FREDERICK PETERSON, M.D., president.
Spinal Accessory Paralysis.—DR. PEARCE BAILEY

presented a man who last March had been operated upon for suppurating glands of the neck. During the operation the spinal accessory nerve had been cut. There had been immediate and complex paralysis of the sternomastoid and trapezius. About 6 weeks later the nerve had been sutured, with considerable improvement in the symptoms. During the past summer a weakness had appeared in the deltoid and in the muscles supplied by the musculo-spiral nerve. There had been considerable return of power. A fairly large incision had been made at the operation in the region of the mastoid. On inspection, the shoulder on the affected side was seen to droop and the scapula hung away from the spine. The only anesthesia observed had been limited to the ear and over the right side of the face—an area corresponding to the supply of the great auricular nerve, which had undoubtedly been cut at the same time. There was now marked hyperesthesia over the distribution of this nerve. When first seen the position of the head had been slightly towards the injured side and a little downward. Dr. E. D. FISHER suggested that there was a psychical element in the case. He said that on pressing along the muscles of the arm slowly there was no reaction, but if done suddenly there was a spasmodic contraction of the muscles of this region. Dr. JOSEPH COLLINS did not think the whole condition had been explained by Dr. Bailey, for, in his opinion, there were symptoms of root involvement over a rather extended area. He could not understand how these could be explained by mere section of the spinal accessory nerve. The tic of the facial muscles and on either side of the neck, and the narrowing of the palpebral fissure appeared to be associated with fibrillary twitchings. This would indicate a rather extensive involvement of the anterior roots in the cervical region. He would also like to know about the condition of the pupils. Dr. F. PETERSON said that he had seen this case before, and had been interested in the complications. He had seen the man before the appearance of the twitchings, and on first noting the latter he had been inclined to assume that it was hysterical. However, after having made the electrical examination he had felt sure that it was not hysterical, but a pressure palsy involving a number of nerves, possibly as a result of sleeping with the arm in an upward position. Dr. BAILEY said that the suppurating gland had been situated deeply underneath the sternomastoid. When first seen by him last April there had been a typical picture of paralysis of the sternomastoid and trapezius, but no symptoms referable to the arm, no tics and no functional disorders. The man had been completely incapacitated for work, and this probably explained his psychical condition. The irritative condition of the face was probably explicable by the formation of new connective tissue in the scar. As soon as his attention had been called to the pressure palsy he had been watched at night and prevented from sleeping on his arm, and this had resulted in immediate and decided improvement. It was probable that in time the man would get fairly good use of his arm.

Facial Hemiatrophy.—Dr. MAX MAILHOUSE presented a man, 20 years of age, without neurotic family history. Twenty-two months ago a discoloration had appeared on the right side of the face below the lower lid. It had begun as a pale, depressed spot. When first seen by the speaker, the right side of the face had been much atrophied, and the beard had been absent on this side. The mouth had been drawn to the right and the right half of the tongue very much atrophied. The apparent prominence of the right eyeball was due to retraction of the lower lid. The hair of the right half of the scalp was grayer than on the left, and was falling out. He had been losing his teeth on the right side. The nasal cartilage was wasted, and its tip was turned to the right. The muscles of mastication were also atrophied, and this was associated with spasmodic pain. There was a fibrillary tremor of the large muscles. The affected muscles reacted feebly to faradization, and normally to galvanism. No scleroderma was found. For the past two months there had been twitching of the muscles on the right angle of the mouth, and at times after laughing, this angle would remain retracted. At such times there was a very tender spot in front of the ear. A blow of moderate severity had been received over the mouth 10 years ago. No other etiologic element could be elicited, and even this one seemed to have but little weight. The atrophy of the tongue seemed to be a strong argument for the theory that this affection is a tropho-

neurosis. DR. C. L. DANA said that he had met with several such cases, and had found them all quite obscure. At one time the view had prevailed that it was a trophoneurosis due to some lesion of the trophic root—a condition very difficult to understand. In one of his cases there had been a typical diffuse trigeminal neuritis occurring in a woman of about 40 years. The attack had begun with herpes and neuralgia, and had been followed by a general neuralgia in the course of the fifth nerve. After this there had been atrophy and some anesthesia, and finally a peculiar pitting of the face, like that from smallpox. In another case, the trouble had begun, as it often did, with pigmented spots and neuralgia, and this had been followed by anesthesia in spots and a typical progressive anesthesia involving all the tissues, including the masseter muscle and the bone. In this woman there had been deafness and some disturbance of vision on the affected side. It was difficult to understand how a trophic or central lesion could cause all these symptoms. A herpes was almost always a sign of peripheral trouble. Another case had been in a woman, who had married at the age of 17. Her husband had died, it was said, of syphilis a few years later, though the woman denied ever having become infected. She had a progressive facial hemiatrophy for a number of years, and had finally developed atrophy on the same side, affecting the arm and the leg. In none of his cases had there been anything indicating the true nature of the etiology. Perhaps the best explanation was that of a peripheral lesion as a starting point. He had obtained no definite results from treatment, perhaps because he had not been able to keep these cases under treatment for a sufficient length of time. If the trouble were peripheral, Dercum's idea of resecting the trigeminus seemed to be worthy of consideration. DR. FRAENKEL asked if any difference had been observed in the behavior of the sweat glands on both sides of the face. DR. MAILHOUSE replied that there had been less sweating on the affected side. DR. JOSEPH COLLINS thought the disease could be explained just as well by a central as by a local lesion. He was inclined to think that the patient just presented had a lesion in the pons, in the area of central representation of the sympathetic nervous system in the pons. The lesion was probably a slowly progressive one such as a gliomatosis. There already seemed to be involvement of the motor nuclei in the medulla oblongata. The enlargement of the pupil would be explained by an irritation of the sympathetic which had gone on to paralytic effects.

Progressive Lingual Hemiatrophy.—DR. C. L. DANA presented in connection with the last case a rather rare form of progressive lingual hemiatrophy. It occurred in a man, 26 years of age, who had had the trouble 3 years, but had been otherwise in perfect health. The half of the tongue was slightly wasting away, and this was associated with fibrillary twitchings. The patient was a healthy young medical student without history of syphilitic infection or nervous heredity. It did not seem to him necessary to suppose that there was a gliosis, for Mendel had already shown that there is a change in the motor root of the trigeminus. Of course, these changes might be secondary to degeneration and partial destruction of the nerve. DR. PETERSON said he was inclined to believe with Dr. Collins, that some central lesion would best explain the condition. He had seen several cases, but all of them in a much earlier stage. In none of them had the tongue or the muscles of mastication been involved, or had they presented the same pupillary phenomena. DR. MAILHOUSE thought the dilation of the pupil might be explained by a similar process involving the sphincter pupillae and causing weakness. Hoffmann had reported some improvement from the use of galvanism for half an hour daily.

NEW ENGLAND.

Dr. Burt Andrews, son of Judge A. G. Andrews, of the Augusta Municipal Court, died January 12, aged 32 years.

The Boston Society for Medical Improvement will hold its first meeting in the new Library Building on Monday, January 21.

Boston Medical Library.—The new library building was formally opened on the evening of January 12, by Dr. David W. Cheever, president. The library has now over 32,000 volumes.

Harvard Veterinary Medical Alumni Association.—At the dinner at the Parker House, Boston, on January 8, the officers elected for the ensuing year were: President, Dr. L. Frothingham, of Boston; vice-presidents, Dr. L. L. Weeks, of Falmouth, Dr. W. E. Peterson, of Waltham, Dr. P. J. Crown, of Boston; secretary and treasurer, Dr. E. W. Babson, of Gloucester; Council, for 3 years, Dr. G. B. Foss, of this city, and Dr. E. A. Madden.

CHICAGO AND WESTERN STATES.

Epidemic of Typhoid.—Seventy-two cases of typhoid fever are reported to the Board of Health of Ashland, Wis.

Smallpox in Kansas.—Dr. W. B. Swan, of the State Board of Health, reports 267 cases of smallpox in the State. The type of the disease is more severe than it was last winter.

Dr. John M. Gaston, who for more than half a century stood high in the medical profession of Indianapolis, Ind., died January 10, aged 82. He was one of the organizers of the Marion County (Ind.) Medical Society.

Crusade of Vaccination.—A crusade of vaccination against smallpox was carried on vigorously at Kansas City, January 8. Doctors invaded many large office buildings and places where people congregate in large numbers, and vaccinated people by the dozen.

Grip Epidemic in Chicago.—According to estimates made by physicians on January 9, there are 100,000 cases of grip in Chicago at present. The last epidemic of grip in this city, together with impure water diseases, increased the death-rate from 21,869 in 1890, to 27,754 in the epidemic year of 1891.

Smallpox in Missouri.—At a meeting of the Camden City Board of Health, January 6, Dr. S. C. James, resident member of the State Board of Health, said that there are cases of smallpox in over 100 towns of Missouri, and that the most vigorous quarantine measures have failed to stop the spread of the disease. New cases are being daily discovered, but the smallpox existing in Kansas City is not of a virulent form, and few deaths are expected to result from it.

Hospital to be Independent.—At the seventh annual meeting of the Norwegian Tabitha Hospital society reports submitted showed that the hospital days for the year were 12,034, and the total expenditures \$12,402.69. A proposition to put the institution under the management of one of the Norwegian church societies was rejected, and patients will be received and treated as heretofore, irrespective of creed or nationality. The hospital officers are: Chief surgeons, Dr. C. Fenger and Dr. A. Hemboe; president, Dr. K. Sandberg; secretary, H. Rommen; treasurer, H. A. Haugan.

Mosquito Blamed for Yellow Fever.—The American Commission in Havana, under the superintendence of Dr. Reed, which has been making experiments at Quemados as to the propagation of the yellow fever germs by the mosquito, has obtained extremely satisfactory results. Dr. Reed says the experiments showed beyond a doubt that there is no contagion from an infected person or from infected clothing, but that the mosquitoes alone are responsible for the spread of the disease. In the course of the commission's investigations six non-immune persons were infected direct by the bite of mosquitoes which had previously bitten yellow fever patients, and five of these developed yellow fever. The last experiment made proved conclusively, Dr. Reed contends, the theory of propagation by mosquitoes. A special building was constructed of disinfected material, and one of the rooms was divided into two sections by a wire mosquito screen. In one section were placed disinfected bedding and clothing, and in the other bedding and clothing from the yellow fever hospital which had not been disinfected. Two non-immunes occupied the two sections. In the former were put several infected mosquitoes. The patient remained in this room only long enough to be bitten, and in four days a pronounced case of yellow fever developed. The patient is now convalescing. The other subject slept in the infected bedding for many nights and has not contracted the fever. Both patients have been sleeping for 20 nights in garments

worn by yellow fever victims and in bedding from the yellow fever hospital. Dr. Reed says they are growing fat, and that in no instance in the course of the commission's investigations has a case of yellow fever developed from exposure to infected bedding or clothing.

SOUTHERN STATES.

Smallpox in Galveston.—Smallpox has broken out to a considerable extent in Galveston. The authorities have ordered that every person in the city should be vaccinated.

Dr. A. B. Richardson has been elected to fill the vacancy in the chair of mental diseases of the Columbian Medical School at Washington, caused by the resignation of Dr. Foster.

Seven Thousand Grip Cases.—Health authorities state that there are now 7,000 cases of grip in Fort Worth, Texas. Smallpox is also prevailing in that city to an alarming extent.

Death of Dr. Harris.—Dr. Charles Morris Bainbridge Harris, son of the late Dr. Thomas Harris, U. S. N., died January 8, at his residence, 1917 Kalorama Ave., Washington, D. C., aged 73.

Savannah Hospital.—By the will of Dr. William Duncan, of Savannah, Ga., who died recently, the Savannah Hospital will become a beneficiary of nearly one-half of his estate, which is valued at about \$80,000.

Dr. W. J. Humphreys, assistant instructor in physics at the University of Virginia, is to be one of the party of scientists to be sent by the Naval Observatory to Sumatra to observe the eclipse of the sun on May 18.

Smallpox at Fredericksburg, Va.—Suspicion of smallpox in the adjoining county of Louisa has led the County Board of Health to order that the public schools of Green Springs and Louisa Court House districts be closed.

Dr. David Caldwell Ireland, a well-known physician, died suddenly January 14, at his home in Baltimore. Dr. Ireland was born at Annapolis, Md., 57 years ago. He graduated from the University of Pennsylvania in 1867. He was president of the Pension Board No. 1, and of the Medical and Chirurgical Faculty of Maryland.

Spring Grove Hospital.—The annual report of the Board of Managers of the Maryland Hospital for the Insane (Spring Grove) shows that the total number of patients was 626. Of these 18 were discharged as recovered, 15 discharged as improved, 41 discharged as unimproved, and 42 died. The number remaining October 31, 1900, was 510.

Presbyterian Hospital's Work.—At the annual meeting of the board of governors of the Presbyterian Eye, Ear, and Throat Hospital of Baltimore, January 12, the following officers were elected: President, W. W. Spence; vice-presidents, J. P. Ammidon, R. M. Wylie, Dr. D. C. Gilman, Thos. B. Gresham; secretary, Dr. F. M. Chisolm; treasurer, John L. Reed.

Maryland State Board of Health.—The Board held its annual meeting January 10. The following officers were elected: President, Dr. W. H. Welch; chemist, Dr. William B. D. Penniman; bacteriologist, Dr. William R. Stokes; inspector, Charles M. Mitten; clerk, M. L. Rullman; laboratory assistant, E. M. White; clerk of vital statistics, E. M. Rullman. Dr. W. H. Welch, Dr. James Bosley, and Dr. J. B. Noel Wyatt were appointed members of the executive committee.

Central Texas Medical Officers.—The Texas Central Medical Association closed its fifteenth annual convention January 9. The following officers were elected for the ensuing year: President, N. A. Oliver, Waco; first vice-president, E. D. Capps, Fort Worth; second vice-president, W. B. Anderson, Brownwood; secretary-treasurer, W. R. Thompson, Fort Worth. New members of judicial council: W. C. Blalock, Kosse; and B. W. D. Hill, Dawson. The next meeting will be held at Temple.

Medical Society of City Hospital Alumni of St. Louis.—The society met in the rooms of the board of education, 9th and Locust streets, on Thursday, January 17, at 8 o'clock P.M. The following papers were presented: **Report of a case of articular rheumatism with fatal heart complications in a child**, by Dr. HUDSON TALBOTT; **Points of interest gathered from some Eastern Hospital**, by Dr. F. G. NIFONG; **Report of cases of infectious disease of kidney** (postponed from January 3), by Dr. H. W. SOPER.

Richmond (Va.) News.—Smallpox is at present epidemic in many counties in this State. As a usual thing, the cases are of a mild type and the death-rate has been remarkably low. There are at present 11 cases in the smallpox hospital of this city.

At the first meeting of the Academy of Medicine and Surgery this year, the following officers were installed: Dr. Stuart McGuire, president; Drs. W. J. Mercer, W. R. Robins and J. M. Winfree, vice-presidents; Dr. M. W. Peyser, secretary; Dr. W. J. Moseley, treasurer.

Death of Dr. Abram Claude.—Dr. Abram Claude died in Annapolis, Md., on January 10. Dr. Claude was born in Annapolis on December 4, 1818. He was the son of Dr. Dennis Claude, at one time surgeon in the United States Army, and was mayor of Annapolis in 1849, 1850, and 1867. During the war Dr. Claude was assistant surgeon in the United States Army; professor of natural science in St. John's College from 1871 to 1883. The deceased was a graduate of St. John's College and of the University of Pennsylvania. He was a man of much learning, great polish, refinement, and invincible courage of conviction.

Laws Wanted by Medical Men.—At the meeting of the St. Louis Medical Society last night a resolution was introduced to appropriate \$250 to aid the committee on legislation of the Missouri Medical Society in promoting whatever measures the committee decides to present to the Legislature at the present session. The committee was appointed at the last session of the Missouri Medical Society to try to secure certain legislation in favor of the medical profession. One of its measures is a law requiring applicants to pass an examination before being registered to practise medicine. The society is also urging measures calculated to eliminate politics from the Missouri Medical Society. The resolution will probably not be acted upon until the next meeting, on January 26.

The Johns Hopkins Hospital Medical Society.—The meeting of January 7, 1901, was called to order by the president, DR. W. H. WELCH.

Typhoid fever without intestinal lesions, by DR. OPIE and MR. BASSETT. Dr. Opie stated that there are a certain number of cases of typhoid fever reported in which no lesions have been found at autopsy in either the large or small intestine, and that very recently a case had come under his observation which belonged apparently to this group. The patient was a child, 10 years of age, with a good family and personal history. The illness began 5 days before admission to the hospital, the first symptoms being headache and backache. There were several movements of the bowels accompanied with pain in the abdomen, and on the following day she felt feverish. On admission to the hospital, temperature was 102.4°, there were typical rose-spots on the abdomen and the agglutination test was positive when the blood-serum was diluted 1:5. The disease appeared to be mild and the temperature ranged from 102° to 104° during the first week. On the thirteenth day after admission nose-bleeding first began and purpuric spots appeared on the face. The coagulation time of the blood, tested with Wright's capillary tubes, was 4½ minutes. The bleeding was difficult to control at times, and on the night of the seventeenth day after admission she passed 60 cc. of bright-red blood from the rectum. A blood-test the next day showed 2,256,000 red corpuscles, 3,000 white corpuscles, and 41% of hemoglobin. Two days later purpuric spots appeared over the face, neck, front and back of the chest and posterior surfaces of the arms. On the twenty-first day bleeding began again from the nose and it was found impossible to control it. The red corpuscles then numbered 1,700,000, leukocytes 15,000, hemoglobin 26%, and the coagulation time was 5½ minutes. She died that day, which

was the twenty-sixth day of her illness. At the autopsy numerous minute ecchymotic areas were found in the heart-muscle, in the lungs, liver, kidneys, and stomach. The small intestine contained a brownish-red fluid, and Peyer's patches were evident in the lower part of the jejunum and throughout the ileum. The solitary follicles of the large intestine were visible and marked by minute points of pigmentation. The retroperitoneal glands and the lymph glands of the mesentery were enlarged. Microscopic examination of the liver showed foci of necrosis similar to those usually found in typhoid fever and in these areas were evidences of cell-infiltration. Sections were made through several Peyer's patches and while there was no evident hyperplasia some sections did show groups of large epithelioid cells similar to those so constantly found in typhoid lesions. Cultures were made from the various organs and the colon-bacillus obtained from the liver and kidneys, and from the liver, gallbladder and kidneys a motile bacillus was obtained which agreed in all respects, when tested experimentally, with a stock culture of the typhoid organism. Notwithstanding the fact that the lesions of the intestine were so slight as to be hardly recognizable, and of such a nature that they might readily have been overlooked, Dr. Opie thought there could be no doubt that this was a case of hemorrhagic typhoid. The hemorrhage from the intestines was apparently not due to ulceration, for no microscopic lesions in the mucosa were noted; it probably was the result of oozing from the mucous membrane of the stomach where there were numerous ecchymoses. Dr. Opie presented a critical review of all the reported cases of supposed typhoid without intestinal lesions and said that he could find no conclusive proof that the infection could occur without some slight lesion of the intestinal tract.

DR. FUTCHER, in discussion, said that this was the second case of hemorrhagic typhoid which had been seen at the Hopkins Hospital where over 1,000 cases of this disease have now been treated. The first case recovered, but the second illustrated very well the hopelessness of endeavoring to counteract the tendency to bleeding in those cases where a hemorrhagic diathesis occurs. All the usual methods adopted to stop bleeding were tried on this patient, including the use of suprarenal extract, but without satisfactory results. DR. WELCH remarked that there was no question that cases of typhoid fever could occur without ulceration of the intestines and referred to the clinical history of some mild cases which would lead one to suspect an infiltration of Peyer's patches and the solitary follicles without actual ulceration. He also referred to a group of cases in which death occurs late in the disease and when one might readily suppose that the typhoid lesions had healed. He believed that a less careful pathological study than that made by Dr. Opie and Mr. Bassett would have led to the report of such a case as theirs as one entirely without intestinal lesions.

Report Upon Bacillus Mortiferous.—DR. HARRIS related the discovery of this new organism and described its peculiarities. The clinical history of the case from which the organism was isolated was practically that which accompanies a liver abscess and at the operation the liver was found to be very much enlarged and to present upon its surface numerous thin-walled abscesses. From the pus of one of these abscesses this new bacillus was obtained. It is very minute and is cultivated with very great difficulty, growing only on media containing as a basis, blood, blood-serum or hydrocele fluid, and then only anaerobically. Experimental work on animals showed that the organism was quite virulent, rabbits usually succumbing within 6 days. The lesions were always emaciation, loss of subcutaneous fat, a tremendous degree of peritonitis and multiple abscesses of the liver.

CANADA.

Dr. Thomas Brown Wheeler, a prominent physician of Montreal, died suddenly on January 11 in the Murray Hill Hotel, New York City.

MISCELLANY.

Obituary.—DR. FRANCIS G. CONNELLY, aged 80, at Baltimore.

Grip in New York City.—From December to March, 1900, there were 5,000 deaths from grip.

Reception to Explorer.—Dr. A. Donaldson Smith, the Philadelphian whose African explorations have gained him renown, was the guest of honor at a reception held January 9, at the Academy of Natural Sciences.

Influenza.—It is estimated that there are probably 500,000 cases of influenza in Greater New York, 7,000 in the city of New Haven, with a total of 40,000 in Connecticut. Conservative estimates by the Buffalo officials place the number of cases at 5,000. St. Louis reports 10,000 cases. It is estimated that 1,500 employes of the great steel company at Homestead, Pa., are afflicted with influenza.

Medical Congress in Cuba.—Active preparations are making for the third Pan-American Medical Congress to be held in Havana, Cuba, February 4 to 6. It is expected that there will be 1,500 delegates present, of whom 500 will be Cuban physicians, 300 or 400 Americans, 200 Mexicans, and others from Argentine, Uruguay, Brazil, Venezuela, Colombia, Peru, Chili, and other Central and South American countries.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended January 11, 1901:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.

Hospital Ship for the Philippines.—Army officers have been sent from Manila to Hong Kong to negotiate the purchase of a suitable vessel for use among the Philippine Islands for hospital purposes. The hospital ship *Relief*, which is being used between some of the ports of the islands, is unable to enter all of the ports, and it is the desire of the Army authorities to secure a smaller vessel which can enter the shallow harbors.

Third Pan-American Medical Congress.—The following is a partial list of titles of papers to be presented at the Third Pan-American Medical Congress, to be held at Havana, Cuba, February 4, 1901:

Section on Medicine.—President, Dr. Carlos Finlay; secretary, Dr. Judson Daland, 317 S. 18th street, Philadelphia, Pa. Etiology, by Dr. Elmer Lee, New York; Physical Diagnosis, by W. H. Vandenberg, New York; Remarks on Tuberculosis, by Dr. Laston H. Montgomery, Chicago; Tuberculosis in Man and Beast, by Dr. John A. Kelley, Brooklyn.

Section on General Surgery.—President, Dr. Tomas Plascencia; secretary, Dr. W. P. Nicholson, Atlanta, Ga. Operative Treatment of Prostatic Hypertrophy, by Dr. Ramon Guiteras, New York; The Bearing of Local Leukocytosis in Surgery, by Dr. E. T. Morris, New York; Gangrenous Hernia, by Dr. T. H. Manley, New York; Treatment of Varicose Ulcers, by Dr. J. Medina, New York; Cocain Spinal Anesthesia, by Dr. G. R. Fowler, New York; The Proximal Foot and Its Effect upon the Knee-joint, by Dr. Michael Hope, Atlanta, Ga.; Surgical Intervention in Uterine Fibroids, by Dr. A. Vander Veer, Albany, N. Y.; Remarks upon Postoperative Psychical Disturbances, by Dr. G. Tucker Harrison, New York; Knee-joint Tuberculosis Differentiation in the Young and Adult, by Dr. J. D. Griffith, Kansas City; Operative Treatment of Inguinal Hernia, by Dr. A. M. Phelps, New York; Some of the General Conditions and Features of Disability Attributable to Personal Accidental Injury, as well as Disability Due to Disease following Bodily Injury, by Dr. L. H. Montgomery, Chicago, Ill.; Remarks on Inguinal Hernia, by Dr. Garmo.

Section on Obstetrics.—President, Dr. Eusebio Hernandez; secretary, Dr. Gustav Zinke, 13 Garfield Place, Cincinnati, Ohio. The Toxicity of the Urine in Pregnancy and Its Relation to Puerperal Convulsions, by Dr. Milton J. Duff, Pittsburg, Pa.; Face Presentation, by Dr. J. A. Lyons, Chicago, Ill.; The Management of a Myomatous Pregnant Uterus, by Dr. W. W. Wathen, Louisville, Ky.; Experimental Investigations on Puerperal Sepsis, by Dr. F. Gaertner, Saginaw, Mich.; The Simultaneous Occurrence of Extra- and Intrauterine Pregnancy and a Tabulated Record of 62 Cases Collected from 1703 to 1901, by Dr. E. Gustav Zinke, Cincinnati, O.; Cholemia and Hemorrhage, by Dr. D. T. Gilliam, Columbus, Ohio; Renal Insufficiency in Relation to Women, by Dr. J. T. Jelks, Hot Springs, Ark.; Clinical Consideration Relating to Cancer of the Uterus, by Dr. A. F. Currier, New York; The Medication and Treatment of Uterine Fibroids, by Dr. W. B. Chase, Brooklyn, N. Y.

Section on Gynecology and Abdominal Surgery.—President, Dr. Gabriel Casusa; secretary, Dr. H. P. Newman, 103 State street, Chicago Ill. Cancer of the Fundus Uteri, by Dr. J. M. Baldy, Philadelphia, Pa.; Treatment of Prolapse of the Uterus, by Dr. H. T. Byford, Chicago, Ill.; Uteral Implantation into the Intestines—a New Method with a Bacteriologic and Histopathologic Study of the Kidney, by Dr. Jacob Frank, Chicago, Ill.; Intestinal Sutures, All Knots Inside, by Dr. F. G. Connell, Chicago, Ill.; The Complications and Degenerations of Fibroid Tumors as Bearing Upon the Treatment of These Growths, by Dr. Chas. P. Noble, Philadelphia, Pa.; Septic Peritonitis, by Dr. C. J. Anderson, Chicago, Ill.; The Angiotribe, by Dr. H. P. Newmann, Chicago, Ill.; Shock in Abdominal Surgery, by Dr. F. B. Turk, Chicago, Ill.; Some Points in the Technic of Hysterectomy, by Both Infra- and Suprapubic Methods, by Dr. W. H. Wathen, Louisville, Ky.; Cocain Anesthesia by Lumbar Puncture in Gynecology, by Dr. J. Riddle Goff, New York; Combined or Multiple Surgical Operations at one Seance in Female Patients, by Dr. R. S. Suttan, Pittsburg, Pa.; When and How Should a Ruptured Ectopic Pregnancy be Operated Upon? by Dr. Paul F. Munde, New York; The Author's Flap Operation for Atrisia of the Vagina, with Demonstration, by Dr. Geo. H. Noble, Atlanta, Ga.; Pelvic Suppuration, by Dr. Joseph Price, Philadelphia, Pa.; Water, Its Uses Internally in Abdominal Surgery, by Dr. W. H. Humiston, Cleveland, O.; Heptotomy for the Relief of Some Conditions Produced by Biliary Obstruction, Dr. W. E. B. Davis, Birmingham, Ala.; Gangrenous Hernia and Intestinal Jointing, by Dr. Thomas H. Manley, New York; Surgical Diagnosis of Abdominal Tumors, by Dr. W. H. Earles, Milwaukee, Wis.; The Technic of Appendicectomy per se and as modified by Combination with Lumbar Appendicectomy and Lumbar Exploration of the Gallbladder and Bile Ducts, by Dr. George M. Edebohls, New York; The Operative Treatment of Carcinoma Uteri, by Dr. E. E. Montgomery, Philadelphia, Pa.; The Pus Factor in Appendicitis, by Dr. Ramon Guiteras, New York; Three Dangerous Operations—Repair of Lacerated Cervix, Rapid Dilation of Cervix, and Curetment, by Dr. John B. Deaver, Philadelphia, Pa.; On the Desirability of Combined Operations in Pelvic and Abdominal Surgery, by Dr. W. P. Manton, Detroit, Mich.

Section on Ophthalmology.—President, Dr. Enrique Lopez; secretary, Dr. John R. Weeks, 40 East 57th street, New York. A New Clinometer for Measuring the Torsional Deviations of the Eye and estimating the Degree of Distortion produced by Cylindrical Glasses,

by Dr. Alex. A. Duane, New York; Carcinoma of the Orbit, by Dr. Shumway, Philadelphia, Pa.; Report of a Case of Removal of the Superior Sympathetic Cervical Ganglion for Non-inflammatory Glaucoma, by Dr. Joseph Mullen, Houston, Tex.; Case of Blindness from Sympathetic Ophthalmitis Complicated with Secondary Glaucoma, Restoration of Vision by two Iridectomies, One with Extraction of Lens and Irido-Cystectomy, and Tynell's Operation of Drilling, by Dr. Charles A. Oliver, Philadelphia, Pa.

Section on Laryngology and Rhinology.—President, Dr. C. Desvernine; secretary, Dr. G. H. Makuen, 1419 Walnut street, Philadelphia, Pa. How to Prevent Stammering, by Dr. G. H. Makuen, Philadelphia, Pa.; The Tonsils as Ports of Entry for Pathogenic Organisms, by Dr. Irving Townsend, New York; Injurious Effects of Forced Breathing upon Voice, Speaking and Singing, by Dr. Carl Seiler, Scranton, Pa.; A Case of Sympathetic Cough Cured by Removal of Spur from the Nasal Septum, by Dr. E. F. Ingalls, Chicago, Ill.

Section on Otolology.—President, Dr. Charles Desvernine; secretary, Dr. J. F. McKernon, 62 West 52d street, New York. Remarks on Sinus Thrombosis, by Dr. T. Y. Sutphen, Newark, N. J.; Symptomatology of Treatment of Sinus Thrombosis, by Dr. J. F. McKernon, New York; A Critical Review of the Literature of Mastoid Diseases. Its Complications, by Dr. S. Oppenheimer, New York; A Brief Resume of Experience with Carbolic Acid in the Treatment of Mastoid Wounds and Chronic Suppuration of Middle Ear, by Dr. Wendell Phillips, New York; Report of Mastoid Cases, by Dr. J. O. McRaynolds, Jr., Dallas, Tex.; Some Remarks on Mastoid Operations as Done in England, France, Germany and America, by Dr. A. Hobbs, Atlanta, Ga.; Importance of an Incision in the Inferior Posterior Portion of Canal in Acute Attical Diseases, by Dr. J. G. Tansley, New York; Review of Otolological Literature for Two Years, by Dr. Wilson, Bridgeport, Conn.; Use of Aqueous Extract of Suprarenal Capsule in Ear Diseases, by Dr. W. A. Bates, New York; Two Cases of Ligation of the Internal Jugular Vein for Infective Thrombosis of the Sigmoid Sinus, due to Purulent Otitis Media. One Recovery and one Death, by Dr. Fred. L. Jack, Boston, Mass.; Artificial Aids to Hearing, by Dr. Ed. E. Dench, New York; Acute Otitis Media and Acute Mastoiditis in Scarlatina, Measles and Diphtheria, a Clinical Report of 5,000 Cases, by Dr. A. B. Duel, New York.

Section on Marine Hygiene and Quarantine.—President, Dr. Louis Cowley; secretary, Dr. H. M. Woodward, surgeon M. H. S., Washington, D. C. Need of a National Health Department, by Dr. L. H. Montgomery, Chicago, Ill.; On the Agency of Parasitic Vermin and Other Insect Pests in the Spread of Disease, by Dr. G. Homan, St. Louis, Mo.; The Necessity for the Organization of Bacteriological Commissions for the Study and Investigation of Quarantinable Diseases under the Formation and Control of the Governing Authorities of the Countries Interested—An Absolute Requirement for the Scientific Management and Betterment of Maritime Hygiene and Quarantine, by Dr. Henry B. Horlbeck, Charleston.

Section on Mental and Nervous Diseases.—President, Dr. Gustave Lopez; secretary, Dr. C. P. Hughes, 3857 Olive street, St. Louis, Mo. Morphism and Crime, by Dr. T. D. Crothers, Hartford, Conn.; Syphilis and Insanity, by Dr. H. Waldo Coe, Portland, Ore.; Trauma as an Exciting Cause of Paralysis Agitans, by Dr. F. S. Pearce, Philadelphia, Pa.; Cerebral Neurasthenia, Observations on Diagnosis and Treatment, by Dr. D. R. Brewer, Chicago, Ill.; Possible Cause of Insanity among Americans in the Orient, by Dr. A. J. Ashmead, New York; Autopsychothyria or the Repetition Psychoneurosis, an Inquiry into a Condition of Morbid Rhythmic Cerebral Automatism and Its Rhythmic Forms of Mental Alienation, by Dr. C. H. Hughes, St. Louis, Mo.; Interrelation of the Nervous System and Female Genitals in the Neurotic Diseases of Women—Subject for general Discussion.

Section on Medical Pedagogy.—President, Dr. Manuel Delfin; secretary, Dr. Otis K. Newell, 13 Central Park West, New York. A Plea for Modern Methods of Teaching in our Medical Colleges, by Dr. J. W. May, Kansas City, Mo.; Hospital Service a Prerequisite for a License to Practise Medicine and Surgery, by Dr. G. W. Galvin, Boston, Mass.; Some Observations Respecting the Value of the Present Methods of Medical Education, by Dr. A. P. Clark, Cambridge, Mass.; The Association of American Medical Colleges—Some of the Work it Has Accomplished, by Dr. D. S. Reynolds, Louisville, Ky.; The Next Educational Revolution—What Shall it be? by Dr. D. B. Cornell, Saginaw, Mich.; Remarks on the Method of Treating Mental Diseases, by Dr. Ira von Gieson; Is the smaller Medical College a Useful Factor in the Advancement of Modern Medical Education, by Dr. W. J. Gillette, Toledo, O.; Function of Chemistry in a Medical Education, by Dr. R. F. Rutan, Montreal, Canada.

Section on Dental and Buccal Surgery.—President, Dr. Erastus Wilson; Secretary, Dr. Eugene Talbot, Columbian Memorial Building, Chicago. Can Interstitial Gingivitis be Prevented, and How? by Dr. M. H. Fletcher, Cincinnati, O.; Tuberculosis of the Alveolar Process and Surrounding Tissues and a Few Methods of Differential Diagnosis, by Dr. G. F. Eames, Boston, Mass.; The Gingivae and Pericementum, by Dr. W. R. Walker, Pass Christian, Miss.; Irregularities of the Teeth and Their Treatment, by Dr. A. E. Baldwin, Chicago, Ill.; Treatment of Interstitial Gingivitis, by Dr. Eugene S. Talbot, Chicago, Ill.

Section on General Hygiene and Dermatology.—President, Dr. Vincente de la Guardia; secretary, Dr. Alvah H. Doty, Quarantine Station, Staten Island, N. Y. Restrictions on Enteric Fever, by Dr. H. B. Baker, Lansing, Mich.; Problem of Infected Well Persons, by Dr. C. V. Chapin, Providence, R. I.; Tricophytics in Reference to Public Hygiene, by Dr. A. Ravogli, Cincinnati, Ohio.

Section on Dermatology and Syphilology.—President, Dr. Henry

Rebelin; secretary, Dr. A. Ravogli, 5 Garfield Place, Cincinnati, O.
Mycosis Fungoides, by Dr. W. F. Breakey, Ann Arbor, Mich.;
The Relationship of Diseases of the Skin to Derangements of Other
Organs, by Dr. Louis F. Frank, Milwaukee, Wis.

Changes in the Medical Corps of the U. S. Army, for the week ended January 12, 1901:

REYNOLDS, Major FREDERICK P., surgeon, is granted leave for two months, on surgeon's certificate, to take effect upon arrival in the United States.

STORY, GEORGE B., acting assistant surgeon, is granted leave for one month, on surgeon's certificate.

WEBBER, First-Lieutenant HENRY A., assistant surgeon, orders relating to him are so amended as to direct him to report in New York City not later than January 14 for transportation to the Philippine Islands on the transport "Wright," and at Manila to report to the commanding general, division of the Philippines, for assignment to duty.

SHOCKLEY, First-Lieutenant Major A. W., assistant surgeon, leave granted December 1 is extended 15 days.

MCARTHUR, ARTHUR W., acting assistant surgeon, will proceed from Chillicothe, Mo., to Fort Yates, to relieve Acting Assistant Surgeon Charles E. Macdonald.

MACDONALD, CHARLES E., acting assistant surgeon, directed to proceed to San Francisco, Cal., for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

JACKSON, THOMAS W., acting assistant surgeon, leave granted December 31 is extended seven days.

BELT, HARRY D., acting assistant surgeon, now in New York City, will report for transportation to the Philippine Islands on the transport "Wright," to sail about January 15, and at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

SCHIMMANN, OTTO, hospital steward, now at the office of the attending surgeon, San Francisco, Cal., having relinquished the unexpired portion of his furlough granted him September 25, will report to the commanding general, department of California, who will furnish him transportation to Manila, P. I., for assignment to duty.

WEBBER, First-Lieutenant HENRY A., assistant surgeon, now under orders to report to the Philippine Islands on the transport "Wright," is detailed for duty as acting assistant quartermaster and acting commissary of subsistence on that transport.

CHAMBERLAIN, First-Lieutenant WESTON P., assistant surgeon, having reported his arrival at San Francisco, Cal., will proceed to Fort Adams for duty.

ALLEN, IRA A., acting assistant surgeon, now at San Francisco, Cal., will proceed to Hot Springs, Ark., and report at the Army and Navy General Hospital for temporary duty.

REYNOLDS, Major FREDERICK P., surgeon, leave on surgeon's certificate granted November 12, is extended two months on surgeon's certificate.

WADHAMS, First-Lieutenant SANFORD H., assistant surgeon, is granted leave for seven days on account of sickness, to take effect from the expiration of the sick leave granted him October 13.

BROOKS, WILLIAM H., acting assistant surgeon, is granted leave for one month to take effect upon his relief from duty at Fort Schuyler.

The following-named acting assistant surgeons will proceed from the places designated to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, where they will report to the commanding general, division of the Philippines, for assignment to duty: HENRY C. BIEBOWER, from St. Edward, Neb.; JAMES E. MEAD, from Detroit, Mich.; FREDERICK W. RICHARDSON, from St. Paul, Minn.

The following-named acting assistant surgeons will proceed from the places designated to New York City for transportation to the Philippine Islands on the transport "Wright," to sail about January 15, and at Manila will report to the commanding general, division of the Philippines, for assignment to duty: TIMOTHY F. GOULDING, from Boston, Mass.; FRANK E. THOMPSON, from Cleveland, Ohio; ARCHIBALD M. WILKINS, from Delta, Ohio.

Changes in the U. S. Marine-Hospital Service, for the week ended January 10, 1901:

WASDIN, EUGENE, surgeon, granted leave of absence for 15 days from January 14, January 5.

WERTENBAKER, C. P., passed assistant surgeon, to proceed to Fontainebleau, Miss., for special temporary duty. January 5.

STIMPSON, W. G., passed assistant surgeon, to proceed to Cripple Creek, Col., for special temporary duty. January 4.

NYDEGGER, J. A., passed assistant surgeon, to proceed to Chicago, Ill., and report to medical officer in command for duty and assignment to quarters. January 5.

DECKER, C. E., assistant surgeon, granted 7 days' extension of sick leave from January 4. January 7.

ANDERSON, J. F., assistant surgeon, having been assigned to duty in the Immigration Service at Liverpool, England, relieved from duty in U. S. Consulate at that port. January 5.

WALKLEY, W. S., acting assistant surgeon, granted leave of absence for 3 days. January 8.

1.—Mr. Langton begins with a description of the descent of the testis beginning at the seventh or eighth month of intrauterine life and reaching the scrotum about birth, the left being about 3 weeks ahead of the right. The processus vaginalis is usually more or less patulous at birth and without any protrusion of the abdominal contents. This is more often true on the right side, which accounts for the greater frequency of congenital hernia on this side. The vaginal process may in rare instances descend into the scrotum and be cut off from the abdominal cavity and the testis remain undescended, and frequently the process is found far in advance of the testicle. He prefers instead of the words "congenital hernia" to say "hernia into the cavity of the tunica vaginalis." The former giving the idea that the hernia has existed from birth, which is erroneous. The points or rings of constriction frequently found in the sacs of congenital hernia he thinks more frequently due to attempts at occlusion than to a displaced neck of the sac. Inguinal hernia occurs 11 times more often in boys than in girls. In fact, in infant boys hernia is 3 times more frequent in the right than in the left side, but in infant girls it is about equal on the two sides. The greater frequency on the right side is due to the later patulency of the tunica vaginalis on this side. Premature children are more liable to hernia at birth than those born at term and the hernia is more apt to be double. Frequently testes are retained in the inguinal canal with accompanying hernia. Langton does not think these liable to become the seat of malignant disease late in years as is often stated. He has examined the records of 7,661 cases of hernia in males and found 4,810 on the right, 2,812 on the left, and 539 on both sides. In 174 cases the testes were misplaced. The proportion of misplaced testes on the right and left sides was as 6 to 4 in favor of the right. A misplaced testis is usually small, soft and flattened and more tender and sensitive than fully developed organs. Congenital hernia is divided into the following varieties: First, hernia into the tunica vaginalis testis. Second, hernia into the funicular process, which descend into the enclosed funicular process of the tunica. Third, herniae into a post tunica vaginalis sac called infantile herniae, where the protrusion is situated behind a dilated tunica vaginalis which is patulous as high as the internal

abdominal ring. Under this head, too, are included the encysted herniae which push before them an invaginated membranous septum into an inclosed tunica vaginalis. The first variety is by far the most common. Protrusion in children is usually intestine alone, the omentum not being sufficiently developed to occupy the sac. He thinks that in nearly all cases of hernia in children under 6 months of age, the hernia is into the cavity of the tunica vaginalis. This variety of congenital hernia may occur at any age, but rapidly decreases in frequency after about the sixteenth or eighteenth year. It is difficult of treatment, narrowing of the serous canal taking place with apparent cure from the use of the truss; but total obliteration is not hopeful and this is especially true of an unclosed canal of Nuck. Records show conclusively that strangulation of the congenital hernia is much more dangerous than that of the acquired variety. Retention of the testes in the inguinal canal with hernia in their unclosed sacs not infrequently accompanies exstrophy of the bladder. Out of the 6 cases of exstrophy seen by Langton, 4 had congenital hernia. The second variety, hernia into the funicular process, is difficult to diagnose, easily reduced, but hard to retain. Under the third variety, infantile hernia, Langton describes its various forms. Another variety of congenital hernia is the so-called "interstitial hernia," which he thinks should be included in variety number one, and which is often described as intermuscular, intraparietal, interparietal, ascending, properitoneal, and hernia *en sac*. In this variety the testes are retained in the inguinal canal in the majority of cases. Interstitial hernia occurs once in every 1,100 cases of hernia in men, once in every 760 cases in women. In the cases studied, the testes were variously misplaced and the corresponding side of the scrotum not developed or absent in nearly all. The various locations of this variety of hernia are then enumerated. In 42 cases of interstitial hernia, 45% occurred in the first year. The greater frequency of interstitial hernia in women is probably due to the distention of the abdominal muscles during pregnancy, as most of the patients in the cases collected had borne large families. [J.H.G.]

2.—Blacker remarks that the causes of postpartum hemorrhage are to be sought in the conditions giving rise to uterine inertia. These may be classified as follows: 1. Feebleness, exhaustion, or malnutrition of the patient, due to a condition of chronic starvation or the result of some disease complicating the labor, such as grave heart-disease. 2. Overdistention of the uterus and undue stretching of the uterine muscles, such as occurs in cases of hydramnios or multiple pregnancies. 3. Exhaustion of the uterine muscle from frequent child-bearing. 4. Pathologic conditions of the uterine wall, as fibroid tumors, marked fatty degeneration, and atony, due to septic infection. 5. Some mechanical hindrance to the contraction and retraction of the uterus, such as the retention of the placenta in utero, or the presence of adhesions between the uterus and surrounding structures. 6. Too rapid emptying of the uterus, either by the application of forceps or after version. 7. Extreme nervous depression and shock, such as may follow the birth of a dead child. 8. The administration of chloroform. 9. Deficient coagulability of the blood, such as occurs in septic affections and in hemophilia. As a means of prevention of postpartum hemorrhage, Blacker recommends small doses of ergot and strychnin combined with iron or hydrochloric acid during the last month of pregnancy. As a routine means of treatment he considers plugging the uterus as greatly inferior to bimanual compression. There are, however, two classes of cases with which the latter method is especially indicated, namely, where the uterus is prevented from contracting and retracting by the presence of adhesions, or by the existence of fibroid tumors in its wall. [W.A.N.D.]

3.—During the last 15 months Mackie has been using calcium iodate as an iodoform substitute and gastrointestinal antiseptic in surgical practice. He claims that calcium iodate acts as a destroyer of bacterial product and also has an inhibitory action on bacterial growth. He recommends calcium iodate in all cases where iodoform is commonly employed. Its advantages are, absence of smell, prevention of hypergranulations, checking of fetor and a decrease in pus-formation, and also that it may be used in aqueous solution as a mouth wash, urethral injection, washing out of the bladder, the vagina, or uterus. Internally he has employed it in checking fermentative changes in the stomach

in 2 grain doses repeated two or three times during the day. He claims that apart from its antiseptic value it possesses some tonic properties. For internal administration the drug should be given in solution. [F.L.K.]

4.—Freeland discusses the following questions under **circumcision**: 1. Is the operation safe? 2. Does the operation interfere with the physical well-being of the individual? 3. Does the end justify the means? The first is answered in the positive; second, in the negative; the third, in the positive. He argues that circumcision not only will prevent oftentimes dysuria, enuresis, urinary retention, balanitis, rectal prolapse, and the aggravation of gonorrhea and other venereal diseases, but that it also greatly lessens the tendency to contract syphilis and the spread of this disease. He produces figures to show how much less frequent syphilis is in the Hebrew race than in other races and attributes the fact to circumcision. In performing the operation he advises the removal of the entire prepuce with the frenum. [J.H.G.]

5.—Dunn believes that the rapid absorption of soft lens-matter from the anterior chamber can only occur after the **reduction of intraocular tension** by the removal of the aqueous. In order to bring this about and to prevent some of the disadvantages caused by the present methods of dissection, the author proceeded as follows under chloroform anesthesia: The pupil having been well dilated with atropin, a broad cataract needle is passed into the anterior chamber of the lens, a vertical and horizontal incision being made in the capsule. The lens matter having been broken up and the needle partially withdrawn, the latter was turned on its own axis, thereby allowing the aqueous to escape slowly. On the fourth day but a small quantity of lens matter remained at the bottom of the anterior chamber, with but a remaining trace on the fourteenth day. He believes that iritis will not follow this operation as a result of **mechanical irritation**, but only when antiseptic procedures have been improperly secured. [M.R.D.]

6.—The **diagnosis** was established by eliminating the following factors: The liver was of normal size, the costal and pulmonary pleurae were not fused, there was no communication between the abdominal and pleural cavities, and the growth was found either springing from or attached to the base of the lung. There was considerable dyspnea, cough, and expectoration, followed by extreme prostration after each attack. Paracentesis thoracis obtained 2½ ounces of a gelatinous material, which, upon microscopic examination, revealed broken-down hydatid cysts without hooklets. The patient died 5 days after admission to the hospital. Upon opening the chest at the autopsy a pint and a half of yellow gelatinous fluid, containing cysts, was obtained. The author believes that the symptoms in the case excluded empyema or pleurisy with effusion, and that its monolateral location eliminated hydrothorax. [M.R.D.]

1. Prevention and Management of Infection of the Breast During Lactation. C. S. BACON.
2. Question of Operation in Appendicitis. FORBES HAWKES.
3. The General Principles of Infant Feeding, with a Simple Method of Home Modification of Cow's Milk. L. EMMETT HOLT.
4. Dyspeptic Asthma. FRANK H. MURDOCH.
5. Some Remarks upon Tuberculosis of Bone. EDMUND OWEN.
6. A Case of Gangrenous Inflammation of Meckel's Diverticulum Simulating Appendicitis. C. R. DARNALL.

1.—Bacon calls attention to the distinction between **infection of the breast and simple hyperemia** or congestion of the breast. The establishment of the milk secretion is always attended with more or less painful congestion of the breast. Infection of the breast, on the other hand, is generally attended with fever, and while it is often confounded with simple congestion it is entirely a distinct process. It is now well known that the fever attendant upon the early puerperium is due to genital wound-infection. Hence the term "milk fever" should be entirely abandoned. If

there is no infection there is no fever. While the simple congestion of the breast is often attended with the tenderness which is characteristic of an infection, other symptoms, as chills and fever, are absent. As soon as these symptoms develop, infection of the breast exists. All measures tending to the improvement of the general health both before and after confinement are most important in the prevention of breast as well as all other infections. The two principles of prophylaxis are to avoid contamination with bacteria and to avoid or heal as quickly as possible the nipple-wounds. For prevention of wounds of the nipple as well as for their cure the nipple-shield is of very great importance. When the nipple-wounds become infected, but before there are any symptoms of general infection or involvement of the deeper breast, the local wound may be treated like similar wounds in other parts of the body. Chills and fever indicate the deeper infection of the breast, which should then be supported and put at rest by a proper bandage. Treated in this way from 80% to 90% of all breast-infections will terminate without abscess. A valuable adjuvant for the treatment of breast infection is the application of cold by means of the ice-bag. If in spite of this treatment tenderness continues and a suspicion of fluctuation exists, aspiration with the hypodermic needle may be performed and if necessary incision may be made. [W.A.N.D.]

2.—Hawkes believes that the surgeon should operate in all cases of **acute appendicitis**, except in those cases of a mild type which exhibit no bad signs or symptoms when first seen, and the patients are evidently recovering from their attack, but that we should operate in these cases later, that is, during the interval. As to whether every patient with appendicitis who has recovered from a first attack should be operated upon before the possible second attack, or this should be postponed until this second attack has occurred, Hawkes' opinion varies. He believes that while a certain number of patients, 23%, never have any trouble or any second attack, the majority, 77%, do have recurrences, any one of which may be distinctly dangerous or even fatal. Therefore operations afford the better chance of an absolute cure. [W.A.N.D.]

3.—See PHILADELPHIA MEDICAL JOURNAL, January 5, 1901, page 35.

4.—F. H. Murdoch reports 5 cases of **chronic dyspeptic asthma**, which form, he says, he has not seen described. The *acute type* presents *asthmatic seizures* after meals, characterized by dyspnea, cyanosis, and irregularity of the pulse. The oppression is relieved by belching and all symptoms disappear if vomiting occurs. The **chronic type** is marked by continuous shortness of breath (not paroxysmal) on slightest exertion. This occurs in patients suffering from gastrointestinal diseases, *without any discoverable abnormalities in heart, lungs, or kidneys*, and yields readily to treatment of the existing dyspepsia. Of Murdoch's 5 cases none complained of dyspepsia, but all came to seek relief from the distressing shortness of breath. Murdoch has found that no *one form* of stomach trouble is responsible for the condition. Three were suffering from *achylia gastrica*.

5.—Owen believes that the **astragalus** is that bone of the foot which is most frequently primarily affected by tuberculosis. Involvement of the ankle-joint by the tuberculous process is indicated by a bulging beneath the tendons in front of the ankle, and also between the posterior portion of the joint and the tendo-Achilles, together with a fulness about the malleoli. The author's experience has been that Syme's amputation has been followed by good results in a large number of cases of tuberculosis in this location. [M.R.D.]

6.—The symptoms in the author's case presented the interesting question as to whether the **diverticulum** became **primarily** or **secondarily** involved. The symptoms were early and constant elevation of temperature, some tympanites, partial intestinal obstruction, which, when relieved, gave rise to improvement in the condition of the patient. Death followed laparotomy. The autopsy showed a collection of seropurulent fluid in the abdominal cavity and engorgement of the peritoneal and mesenteric vessels. The diverticulum of Meckel was gangrenous, perforated and contained about an ounce of foul-smelling fluid. The author believes that the temporary alleviation of the symptoms was mainly due to the hypodermoclysis of normal salt-solution. [M.R.D.]

Medical Record.

January 12, 1901. [Vol. 59, No. 2.]

1. Coffee as a Beverage and its Frequent Deleterious Effects Upon the Nervous System: Acute and Chronic Coffee Poisoning. WILLIAM M. LESZYNSKY
2. An Improved Method of Performing Suprapubic Cystotomy. C. L. GIBSON.
3. Some Remarks on the Modern Surgical and Medical Treatment of Epilepsy. L. PIERCE CLARKE.
4. Report of a Case of Primary Glioma of the Optic Nerve. REDMOND W. PAYNE
5. The Choice of Suture for the Patella. EDWIN M. COX.

1.—The deleterious effects arising from the habit of coffee-drinking are discussed by Leszynsky. One-third of the coffee crop of the entire world is consumed in the United States. He points out the fact that children are especially susceptible to the effects of coffee, tea, etc., and believes that these drugs are frequently the unsuspected cause of **insomnia, night terrors**, and some **intellectual precocity**. He distinguishes between **acute** and **chronic** coffee-poisoning. When taken in sufficient quantity by those unaccustomed to its use it produces **excitability** even to the point of **delirium**. In the **chronic** form it gives rise to a depressive form of **neurasthenia**. It closely resembles chronic alcoholism, for which it is frequently mistaken and with which it is sometimes associated. Guelliot has studied carefully this form. He states that **digestion** is first deranged. At times there is **epigastric pain** radiating to the dorsal region. It was similar to the other **neuralgic pains** from which these patients suffer. The **pulse** is slow, soft, and compressible. The **tremor** which is present, at times, disappears after a dose of coffee just as in chronic alcoholism. **Sexual impotence** in the male and **profuse leukorrhea** in the female are prominent symptoms. It has been observed that confirmed coffee drinkers have a slow pulse (from 40 to 60). In treating the condition, which is frequently not diagnosed, the stimulant should not be absolutely withdrawn, but a morning cup of coffee allowed. The author recommends **nerve sedatives** and **tonics**, and at times the **rest-cure** is necessary. Most cases recover in from three to six months. [T.L.C.]

2.—Gibson under this head discusses the application of Kader's operation of gastrostomy to the establishment of drainage of the urinary bladder. In this operation the author hopes to gain: (1) Effective drainage of the bladder without leakage; (2) rapid closure of the fistula on discontinuance of the drainage; (3) the creation of a permanent sinus which should allow of permanent but periodical catheterization of the bladder, and, in the intervals, owing to its valve action, prevent escape of urine and do away with the discomfort of wearing a tube or dressing. His experience leads him to believe that the first two can be more readily obtained by this operation than by any other, and but for the want of a peritoneal covering to the bladder he thinks that the third also could be easily obtained. He believes that further experimentation will result in the accomplishment of this. [J.H.G.]

3.—Clarke urges the study of the pathological changes in the brain of epileptics. He thinks that medical treatment should invariably precede and follow operation. From the operative cases he would remove the idiopathic epileptics in whom the seizures have a definite form of invasion. The brain in such cases is epileptogenic, one zone being only a little more excitable than another. In Jacksonian epilepsy with well-marked trauma and no neurotic family history trephining may be advised if the epilepsy has not existed for more than 2 years. He thinks that surgeons report cures too early after operation. Some cases are made worse by operation. Operations for the purpose of relieving intracranial pressure in epilepsy is not to be advised, the pressure being the result and not the cause of the convulsions. He thinks Kocher's good results in these cases has been due largely to their careful selection and to his postoperative bromid treatment. Many cases of idiopathic epilepsy are due to infantile cerebral palsies. When such a history exists, operations should not be done. The opening in the skull in operations for epilepsy should not be closed with bones as a relief from pressure is of advantage. Medical treatment, he concludes, as follows: 1. By a combination of diet, regular occupation,

and personal hygiene, the bromids give the best results in treating idiopathic epilepsy. 2. The bromids, singly or combined, still remain our chief sedative for the epileptic state—in the young epileptic to secure a possible entire suppression of attacks and ultimate cure of the disease; in the adult, an amelioration of frequent paroxysms and comparative physical and mental comfort. 3. The bromids to be effective in chronic and long-standing cases must be given in large daily doses to suppress convulsions, from 300 to 400 gr. if necessary. They should be given gradually to find the sedative level, at which level it is the physician's principal duty to maintain them with physical and mental comfort to his patient. 4. Hot and cold baths, high enemas, alimentary antisepsis, and massage are absolutely essential to successful bromid medication. 5. Bromin is a worthy substitute for the bromids in many cases in which the latter are contraindicated or cannot be given in high dosage. 6. Salt-starvation or semi-salt starvation is a great adjuvant to the bromid treatment, and should be thoroughly tried in all cases in which bromids or bromin are apparently contraindicated before they are discarded. [J.H.G.]

4.—Payne's patient was a female child, 2½ years of age, with negative family history. The personal history showed that in the right eye there were signs of convergent strabismus shortly after birth, with the appearance of a gradually progressing exophthalmos 1 year later. There was almost an **entire limitation** in the downward movement of the eyeball but with power of moving the eye outward almost to the median line. Palpation of the globe met with resistance and 1 week before operation a small body could be felt at the temporal side. Pupillary reaction was sluggish and in the fundus some postpapillitic changes were noticed. The diagnosis of a benign tumor pressing upon the optic nerve was made. Upon laying open the external canthus, it was found that the nerve was evaginated and that its sheath enveloped the tumor. After exenteration, microscopic examination of the tumor showed destruction of the nerve-tissue which was replaced by glia cells. In addition to a resumé of the literature, the prognosis and pathologic histology of ocular and orbital neoplasms are discussed, together with the relative malignancy of optic-nerve growths. [M.R.D.]

5.—Cox, after calling attention to the disadvantages of wire as a suture, urges the use of large, plain or chromicized **catgut** in the fixation of fractures of the patella, and gives the histories of 3 cases showing excellent results from the use of this suture. [J.H.G.]

1. Splenic Anemia—Anemia with Enlargement of the Spleen. ALOYSIUS O. J. KELLY.
2. Some Diagnostic Details. EDGAR DARNALL.
3. On Gonorrheal Cystitis in the Female. F. BIERHOFF.

1.—A. O. J. Kelly reports a case of **splenic anemia** in a girl of 22 years. The girl while never robust was fairly well until May of 1899. Towards the close of that summer pain began in splenic region which she attributed to a fall which she had recently sustained. The splenic dullness extended from the eighth interspace to two fingers' breadth below the free margin of the ribs, and anteriorly about the same distance beyond the ribs. The organ was distinctly palpable. It was hard and regular in outline and the notch was plainly made out. The region was slightly tender. On February 14 the blood examination showed 50% of hemoglobin and 8,200 leukocytes. The urine showed no sugar or albumin. There was a basal systolic murmur present, the only cardiac symptom. She had two attacks of articular pain diagnosed as rheumatism—once in the hip, then in the right wrist. Sweats were frequent during March and April and then ceased entirely. The patient's condition first improved under nux vomica and Fowler's solution, but the improvement was only temporary and there followed progressive decline. Splenectomy was suggested, but the patient would not submit to the operation. Fever was present throughout the case, ranging on an average between 100° and 103°. Bleeding from an unusual source, the genitals, also occurred. Towards the close of the case (the patient died June 19, 1900), the dyspnea became extreme. This with the anemia and enlarged, tender spleen completes the clinical picture. The superficial

lymphatic vessels were not enlarged. No postmortem was obtained, so that the condition of the deep lymphatics was not ascertained. The differential diagnosis from ulcerative endocarditis was not an easy matter for some time during the course of the case. [T.L.C.]

3.—Bierhoff believes that many cases of chronic and acute **gonorrheal prostatitis** may frequently simulate acute or subacute cystitis. For this reason he believes that without cystoscopy or opening of the bladder, no positive diagnosis can be made in the male. Of 92 cases examined by the author, 67 were catarrhal, and 25 suppurative. Among these three were only 5 cases of gonorrheal cystitis, and those were found among the suppurative variety. In these cases the diagnosis of gonorrheal cystitis was made from an examination of the urine and cystoscopy. In all of the cases the spread of the disease beyond the originally infected area was prevented. In all cases of acid cystitis the author recommends the microscopic examination of the urinary sediment which will probably disclose the fact that there are more cases of true gonorrheal cystitis than has been supposed. He believes that if appropriate measures are employed before and after cystoscopy in the female during a gonorrheal cystitis that the dangers of this form of instrumental examination are not so great. [M.R.D.]

2.—The great majority of cases of epiphora are amenable to the usual conservative treatment which consists of astringent and antiseptic collyria, syringing and probing, and occasional treatment of the nasal cavities. In spite of a judicious selection and skilful application of these methods there remain a considerable number of cases which are not relieved. These are the cases for which something more radical must be done, and any method of treatment that promises a quick and sure relief from such a condition is worthy of attention. Such a method, it is claimed, is to be found in **extirpation of the lachrymal sac and gland**. In the case of a woman with an absolutely impermeable nasal duct and a lachrymal sac distended to the size of a small lemon by the long duration of the disease, the sac was filled with mucus, which was infected with ozena, and which could be expressed in large quantities into the conjunctival sac at any time. The appearance and the odor were disgusting, and the patient was anxious for any operation to gain quick relief. The lachrymal sac was removed and the disease was cured. Removal of the sac takes away the source of irritation, and not only does away with the disease of the sac and its dangers, but diminishes the flow of tears materially. The removal of the larger lachrymal gland causes surprisingly little diminution in the apparent moisture of the conjunctival sac. It is only when the eye is exposed to stimulus that the difference is usually apparent, and then the diminution is relative. There is never an absolute dryness by any means. There are some cases in which removal of the gland without the removal of the sac seems to promise relief, and if so, is to be preferred. The dangers of this **radical treatment of lachrymal diseases** are: disfigurement, orbital abscess, injury to the optic nerve and the cornea during the operation, and ptosis. The possibility of excessive dryness is conceivable perhaps, but has never occurred as far as Lancaster is aware. The history of 5 cases is given. [J.M.S.]

3.—Parks reports the case of a woman, aged 35 years, who was nearly blind. The right eye was undeveloped and there was a capsuloretaceous cataract in the left eye. A very large flap was made and a large iridectomy was done as a first operation. Thirty-seven days after the first operation the cataract, which was found to be more capsular than cre-

taceous, was removed. Five years after the operation the patient reads the newspapers without glasses; the visions is 4, and she wears a 4 or 5 D. for distance. [J.M.S.]

4.—Treated editorially.

5.—Cobb reports the case of a girl, aged 5 years, who was suffering from enlarged glands on both sides of the neck, just below the angle of the jaw. The history of the case was as follows: A child without history of previous trouble with the nose or throat had diphtheria at the age of 2 years and had a purulent discharge from the nose following this attack; 2 years later enlarged tonsils and adenoids are removed, and 1 year after the operation the patient still had a purulent discharge from the nose and a cervical adenitis following an acute coryza. There can be no doubt but that every case of adenitis in the cervical region is as truly the result of infection as adenitis in any other part of the body. The author enters an earnest plea for the treatment of these cases on the same lines that govern the treatment of adenitis in any other part of the body. There is no evidence that any considerable proportion of these cases of cervical adenitis is due to tubercular infection, and attention is called to the purulent or mucopurulent diseases of the nasal cavities as a possible source of infection. Infection having taken place and the discharge once established, absorption will sooner or later occur, and the lymphatics of the nose being directly connected with those of the neck, a **cervical adenitis** may result at any time, and, unless the **purulent rhinitis** is cured, the cervical adenitis will run a protracted course. The purulent discharge from the nose may not cause a cervical adenitis for some time, because the retained secretion is very largely contained in bony cavities, but it eventually denudes the mucous membrane over which it flows and then some condition, such as an acute cold, blocks the flow of the discharge and absorption of the retained secretion takes place. So long as the source of infection remains unhealed, it is hardly reasonable to hope to cure the adenitis. [J.M.S.]

1.—Anders calls attention to that **period in pulmonary tuberculosis which precedes the presence of tubercle-bacilli in the sputum**. He refers to the fact that this stage is not synonymous with the "pre-tubercular stage." The stage before the appearance of the bacilli is frequently a long one. In support of this he quotes Allbutt and Turban. In referring to the etiology of the affection he calls especial attention to heredity. Under physical examination he mentions in detail the various modes of onset, calling particular attention to "invasive symptoms and conditions such as pleurisy, gastrointestinal symptoms, hemoptysis and onset with symptoms of laryngitis." He calls attention to the importance of taking systematic thermometric records of the entire day for at least several days in succession. He cites the value of the tuberculin test and quotes 3 cases showing its value. He further refers to the value of the x-rays as diagnostic aids in incipient cases. Under treatment he calls especial attention to the value of "equability of climate with an abundance of sunshine." He further insists upon the

importance of proper nutrition. Among medicinal agents he prefers creasote, cod-liver oil, and the hypophosphites. A valuable bibliography is attached at the end of the article. [J.S.]

2.—Cohen gives a review of the **relative importance of valvular and muscular lesions of cardiac origin**. He concludes with a summary that the most important point to be taken into consideration therapeutically and as to prognosis is not the site and nature of the valvular lesion, but the condition of the heart-muscle, with the exception of mitral stenosis, in which he lauds the use of aconite to reduce excessive muscular effort when compensatory hypertrophy is not sufficient. [J.L.S.]

3.—Bishop, in discussing **myocarditis**, calls attention to the fact that it is eminently a clinical disease and that the postmortem findings do not always coincide with the clinical manifestations. Many of the changes in the heart-muscle are dependent upon pathologic changes in the arterial system. A fatal attack of angina may be brought about in a damaged heart through temporary anemia. He calls attention to the fact that many acute cases of myocarditis are of syphilitic origin. He divides myocarditis into two clinical classes—those which are due to infectious diseases and those which are due to diseases of the blood-vessel. He believes that in persons beyond middle life who are the subjects of severe attacks of pain referable to the left shoulder and left breast it is reasonable to suspect myocardiac disease, and such cases should be carefully investigated. Bishop says that it is reasonable to suppose that the pain of cardiac disease is due to the fact that the nerves of various viscera and the nerves of the corresponding portions of the body are connected. Irregularity of the force and rhythm of the heart's action he believes is an early symptom. The character of the pulse is also of important diagnostic value. He states that myocarditis is quite common in colored people on account of syphilitic infection. He gives the report of several cases of myocarditis. [F.J.K.]

4.—Morrissey in discussing the prognosis in cardiac affections comes to the following conclusions: That the condition of the cardiac walls, the condition of the lesion and the time it has existed should all be taken into account when hearing a heart-murmur. The individual should also be taken into account, especially pertaining to his occupation and temperament. It should be remembered that murmurs are not always indicative of endocarditis. In life insurance work too much importance should not be placed upon the presence of a murmur, if the heart still maintains its compensatory power, particularly if the occupation of the patient is not laborious and he has passed the age when rheumatic fever is liable. Morrissey states that aortic stenosis is a favorable lesion from a prognostic standpoint as regards duration of life. Too much importance cannot be laid upon the fact that a patient should not be told that he is suffering from cardiac disease if the condition be trifling, for neurasthenia is apt to develop. Repeated examinations should be made by the physician in cases of cardiac disease. [F.J.K.]

5.—Valentine gives an elaborate description of the method of **surgical asepsis of the urethra and bladder**, together with the demonstration of the autoirrigator, a device which he has employed with a considerable degree of satisfaction. He claims that this instrument enables the surgeon to perform urethral and intervesical irrigations anywhere. It offers likewise a safe and convenient means of anterior urethral irrigation in gonorrhea, when the patient cannot visit his physician for the purpose. Also it furnishes a convenient addition to the instrument-bag for performing ante-operative and postoperative irrigation of the urethra and bladder. It is also a most convenient apparatus for aseptic catheterism. [W.A.D.]

6.—Syms urges upon the profession the importance of the early recognition of obstructing prostatic hypertrophy. He insists that they should submit such patients to a radical operation before cystitis, prolonged pain, infection and fatigue place them in such a condition that they are unfitted to undergo a surgical operation. Nothing can afford relief to the patient except some procedure which will remove the obstruction to the outflow of the urine. There are but two methods of treatment which deserve favor in the minds of the profession, namely: prostaticectomy, and secondly, pro-

tomy performed by means of an electric cautery knife, the operation being known as that of Bottini. [W.A.N.D.]

7.—According to Townsend, the **constitutional treatment of tuberculosis of the knee-joint** should be largely climatic, together with close attention to any organ of the body which is not in perfect condition. Complete rest in bed is preferable to the ambulatory treatment if the patient's joint is tender. Local treatment consists in proper protection of the articulation, perfect rest of the joint, the prevention or correction of deformity, the removal of the tuberculous process, and the treatment of any complications that may arise. To prevent deformity of the knee, plaster of Paris, leather, silicate of sodium or other materials may be used. Care must be taken, however, to see that they are made sufficiently long in order to accomplish the desired result. The removal of local tuberculosis includes the operations of arthrectomy, excision, and amputation, according to the nature of the case. In adults excision is indicated in a large number of cases, but only exceptionally in children. [W.A.N.D.]

8.—Beach endorses the suggestion of Seguin, that the proper way to educate feeble-minded children is the education of the senses, and the more thoroughly this education is conducted, the better will be the training which can afterwards be given. He especially refers in this article to the education of the sense of touch, which, in feeble-minded children, is much more dull than in ordinary children. Such patients do not suffer pain to the same extent as healthy children. The training consists in efforts directed toward the promotion of coordination and the cultivation of the finer muscular movements. Kindergarten occupation may prove especially serviceable in these cases. Children raised in the country are especially suitable cases for cultivating successfully this deficient sense. [W.A.N.D.]

9.—Rosenberg and Aronstam believe that the practice of euthanasia would, in the long run, cause more harm than good. They are convinced that it is far better for the welfare of humanity to let a few suffer rather than run the risk of creating crime and criminals, which they believe would result from the too frequent production of euthanasia. In no case and under no circumstances should the physician intentionally or directly cause death. [W.A.N.D.]

10.—Johnson reports the **removal of a piece of steel from the vitreous** with an electric magnet devised by him. A chip struck the cornea causing an oblique wound extending from limbus to limbus at the upper inner quadrant, thence through the iris, causing prolapse of the latter, and through the lens into the vitreous. The results indicated that the eye-ball could be preserved with a probable later improvement of vision (patient could see shadows after operation) by operative assistance. [M.R.D.]

6. Dorsal Dislocation of the Trapezoid. JOHN GLENDON SHELDON.

1.—Preble and Hektoen report a case of **multiple fibromata of the nerves with arthritis deformans**. The patient, a female, aged 35, gives a family history which has no bearing upon her own condition. The first tumor appeared upon the forehead when the patient was very young, and after a short interval many other tumors developed in different parts of the body. Joint changes showed themselves some years after the formation of the tumors. The smaller joints in the hand were affected first. The tumors were almost without exception painless, and varied in size from time to time. The patient complained of pain

in the abdomen, legs, and feet; walking soon became impossible. The neoplasms on the forehead were arranged in string-like tortuous masses, the largest one being about the size of a small bean. The tumors of the body, neck, and limb varied from the size of a pinhead to the size of a nut. In the deeper tissues the tumors were arranged parallel to the long axis of the body. They permitted of lateral motion, and were not attached to the skin. The arthritic deformity involved the joints of the hand, wrist, knee, and hip. The movement of the jaw was limited, and curvature of the spine was present. The joints of the knee and hip were ankylosed. The nervous system showed no alterations, and the patient was fairly intelligent. Gangrene of the toes developed 10 days before death. Upon postmortem examination the important pathologic lesions were the joint changes, and the fibromata, which appeared to spring from the nerve sheaths. The joints of the wrist, hand, ankles, and feet were especially involved; some of the joints were apparently completely disorganized. The tumors were connected with many of the nerve trunks. The anatomic diagnosis was: "Multiple fibromata of the cerebrospinal and sympathetic nerves; compression of the spinal cord; polyarthritis deformans with kyphoscoliosis, ankylosis, and contracture; moist gangrene of the foot; decubitus; chronic dermatitis of the left leg; inflammation of the frontal sinus; chronic nephritis; marasmus." The literature in regard to these new growths was then carefully reviewed. [F.J.K.]

2.—Opie in an article on the **relation of cholelithiasis to disease of the pancreas and to fat necrosis** directs particular attention to the occurrence of pancreatic disease as a complication of gallstone colic. He mentions two ways in which the pancreas may be involved. 1. As inflammatory changes are not infrequently dependent upon passage of gallstone such inflammation might involve the pancreas by extension. 2. A gallstone lodging at the orifice of the common duct may occlude the main pancreatic duct and favor the growth of microorganisms in the accumulated secretion, and even the secretion if retained in the pancreas might produce pathologic changes. Bilser described disseminated fat necrosis in 1882. This necrosis involves the fat in the neighborhood of the pancreas such as the omentum, subperitoneal fat and mesenteric fat, less frequently the subcutaneous and pericardial fat. Opie refers to Langenhans as demonstrating that the necrosis is associated with the separation of the fat into fatty acids which are insoluble and therefore remain in the cell, and into glycerin which being soluble is carried away. He also mentions the researches of a number of investigators who believe that this necrosis is dependent upon the pancreatic secretion finding its way out of the gland, and that the fat-splitting ferment of the pancreatic juice is directly responsible for this pathologic condition. In his own experiments he has shown that ligation of the pancreatic duct in the cat is attended with extensive fat necrosis. The administration of pilocarpin hastens this pathologic change. The occlusion of the main pancreatic duct does not in every case prevent an outflow of the secretion into the intestine on account of the communication of the duct of Wirsung in the gland with the duct of Santorini which opens into the duodenum. Schirmer's observation on the relations of the two ducts are mentioned: Out of 104 bodies, 65 were found which had an accessory duct opening into the duodenum, and that there was an anastomosis of the main duct with a smaller duct within the organ. One body showed 3 distinct openings into the duodenum. Four cases revealed a single pancreatic duct opening just above the diverticulum of Vater. In 34 cases the smaller duct did not open into the duodenum or anastomose with the larger duct. From this variation in the anatomy of the ducts it is shown that slightly more than one-third of the cases of gallstone obstruction at the mouth of the common duct would be associated with retained pancreatic secretion. A lengthy report of a case is given: The patient, a male, aged 47, was admitted to the Johns Hopkins Hospital (service of Dr. Osler), gives a previous history of jaundice, abdominal pain and fever lasting for 3 weeks. These symptoms occurred 6 months before the present illness. Eighteen days before his admission he was seized with vomiting and severe general abdominal pain which lasted for 5 days. He was constipated and there was abdominal distention. His temperature was irregular, varying from 100° F. to 103° F., with chills. The pulse varied from 100 to 120. Abdominal distention and

some abdominal pain and tenderness persisted. Upon examination a resistant mass was detected which occupied the right hypochondriac region, the right half of the epigastrium, and the upper half of the umbilical region. The leukocytes numbered 18,300. The urine is clear, the specific gravity 1.017; sugar is not present, but there is a trace of albumin. The temperature varied between 99.2° F. and 104.8° F. Another count of the leukocytes showed 19,500 per cubic mm. The diagnosis of suppurative pancreatitis was made and the patient was operated upon under cocaine anesthesia. A large abscess was evacuated. Death followed 4 hours after the operation. The autopsy was performed 3 hours after death. An abscess was discovered occupying the position of the lesser peritoneal cavity. The pancreas was large and firm and of a reddish color. Fat necrosis was found in the fat of the abdominal walls, omentum, mesentery, in the fat anterior to the bladder, in the peritoneal and retroperitoneal fat. A gallstone, measuring 7 mm. in diameter, was found near the orifice of the common duct. The bile ducts were dilated, but the pancreatic duct was not. The gallbladder contained over 100 stones. Upon microscopic examination the areas of fat necrosis showed necrosis of the fat cells, but the outlines of the cells were still preserved. The pancreas shows marked chronic interstitial changes and dilations of many of the acini. There are also some necrotic areas and the evidences of former hemorrhage. Inoculation made from the abscess wall revealed cultures of the *Bacillus coli communis*, the *Bacillus lactis aerogenes* and the *Bacillus proteus vulgaris*. From the clinical and pathologic evidence presented it was reasonable to believe that the cause was primarily due to a gallstone, thereby causing obstruction and retention of pancreatic secretion. A brief history of 7 other cases is also given in which a calculus was lodged in the common duct near its orifice. Six of these cases were accompanied by fat necrosis and some were associated with hemorrhage. Thirty-two cases of pancreatic disease and fat necrosis in association with cholelithiasis are tabulated from literature. A case of Phulpin is cited with the report of the autopsy in which the anatomic diagnosis was interstitial pancreatitis and peripancreatic fat necrosis following obstruction of the pancreatic duct from a gallstone in the mouth of the common duct. The following conclusions are drawn if the gallstone should lodge in the orifice of the common duct and cause compression of the pancreatic duct: 1. With biliary colic and sudden attack of epigastric pain, vomiting and collapse, death may occur in 48 hours. The pancreas will be found enlarged, with blood infiltration into the organ and surrounding tissues and perhaps some fat necrosis. 2. Death may not follow in 48 hours, but jaundice develop and the pancreas may become infected with the formation of an abscess. Under such circumstances the symptoms of sepsis will arise, and death occurs after the lapse of some weeks or months. 3. Repeated or long-continued obstruction of the pancreatic duct by gallstone may cause chronic interstitial changes in the pancreas. [F.J.K.]

3.—Gordinier and Lartigau report a case of **typhoid pleurisy**. The patient, a physician, aged 57, seen by Gordinier on July 14, 1899, gave a previous personal history of an attack of inflammatory rheumatism at the age of 16, which lasted for several weeks, at 20 he had typhus fever, and at 43 he had typhoid fever. This illness lasted for 4 months, and since the attack of enteric fever he has enjoyed comparatively good health, except that he has suffered at times from shortness of breath upon exertion and slight edema of ankles. The present illness was marked by loss of appetite, malaise, headache, constipation, muscular and joint pain, and colicky pain in the abdomen. On July 10, 1899, he was confined to his bed, upon examination the patient presented cyanosis of the lips, finger-tips, and ears, the respirations were hurried, and the pulse was small, irregular and rapid (120), his temperature 103° F., and the tongue was coated. Tympanites, tenderness over the right iliac fossa, enlargement of the liver and spleen were noted, but rose spots were absent. Physical examination revealed a double mitral lesion with displacement of the apex to the left and reduplication of the second sound. The lungs showed congestion and some edema posteriorly, the urine gave a diazo-reaction, the Widal-reaction was negative, leukocytosis was absent, and the plasmodium malarie was not found in the blood.

A provisional diagnosis of typhoid fever with failing heart compensation and edema and congestion of the lungs was made. After some days the patient improved, especially those symptoms relating to the heart and the lungs, but fever continued up to this time. The treatment consisted in the administration of digitalis, strychnin, and nitroglycerin. Upon physical examination on July 17 the signs of a right-sided pleural effusion were elicited, and two days later the signs were very marked. Aspiration was performed and two quarts of a greenish, opalescent fluid were withdrawn. The operation was repeated on two subsequent occasions. From the pleural exudate the *Bacillus typhosis* was isolated in pure culture. [F.J.K.]

4.—Litigau reports a case of **gonorrheal ulcerative endocarditis with cultivation of the gonococcus**. The patient, a male, colored, aged 20, was admitted to the Roosevelt Hospital, August 4, 1900. It was ascertained that the patient had urethral disease for 8 weeks previous to his admission to the hospital, and for 6 weeks before he had two or three attacks of chills and fever per week. One day before admission he lost the power of speech. On the day he entered the hospital his pulse was 126, his respiration 32, and his temperature 103° F. His tongue was coated and his lips swollen. An inguinal gland on the left side was found enlarged. A loud systolic murmur was heard at the apex and was transmitted to the left. Several days later (August 6) he developed low muttering delirium. A circumcision was performed. The urethral discharge ceased after some days of treatment with irrigations of potassium permanganate. A blood examination on August 18 showed a leukocytosis of 11,400 with a slight anemia. Later he developed a swelling of the right elbow joint which only lasted a day, but tenderness persisted. Fever was present during the illness and death occurred on September 5. Postmortem examination showed ulcerative endocarditis of the mitral valve with eccentric hypertrophy of the left heart. Urethritis, edema and congestion of the lungs, splenic enlargement with infarction and cloudy swelling of the kidneys and liver were found. Upon microscopic examination of the urethra destruction of the epithelium was found, and round cell and polymorphonuclear cell infiltration of the deeper tissues. A diplococcus resembling the gonococcus tinctorially and morphologically was present upon the surface of the membrane and in the tissues beneath. Sections of the inflamed mitral valve segment showed necrotic areas, leukocytic and round-cell infiltration. There were also biscuit shaped micrococci as a rule arranged in pairs and some were within the leukocytes. Inoculation from the valve lesion upon a blood serum tube gave a growth of two smaller grey colonies at the end of 48 hours. These colonies consisted of micrococci which were morphologically and tinctorially identical with the gonococcus. A similar result was obtained from an inoculation from the heart's blood. The *Bacillus coli communis* was found in the liver, gall, and urinary bladders. He reviews 5 other cases in which the gonococcus was obtained in culture: (1) That of Thayer and Blumer, who obtained gonococci from the blood during life and demonstrated the microorganism microscopically after death; (2) that of Dauber and Burst, who demonstrated the gonococcus in pure culture in the heart's blood; (3) that of Thayer and Lazear, who obtained cultures of the microorganism 3 times during life and from the lesions of the pericardium and heart; (4) that of Rendu and Halle, who also obtained culture during life from the endometrium and heart lesions after death; finally (5) that of Lenhartz, who produced urethritis accompanied by a purulent discharge with the gonococci which were obtained in pure culture from an aortic valve lesion. Lartigau draws the following conclusion: "1. Gonococcal urethritis may be the starting point of a fatal septicemia induced by a pure infection with the gonococcus. 2. Endocarditis and arthritis are occasionally complications of such an infectious disease. 3. The endocardial process may be incited by the gonococcus without the association of other organisms." [F.J.K.]

5.—Ford reviews the literature of cirrhosis of the liver with special reference to the frequency of **obstructive biliary cirrhosis**. He gives a report of 21 cases collected from literature, and of 3 cases hitherto unpublished as occurring since 1882. He mentions the researches of J. Wickham Legg and J. M. Charcot as being the first observers to distinguish obstructive biliary cirrhosis as a distinct pathologic

condition. He also briefly cites the results of the experiments of Legg "on the changes in the liver which follow ligation of the bile ducts," stating that out of 16 cats in which the common bile ducts were ligated, 12 developed enlargement of the liver, increase in the interlobular connective tissues, and atrophy of the liver-cells. Results in many respects similar to those of Legg were observed by Charcot, by tying the bile-duct in rabbits. Both of these observers naturally could not exclude the ill effects produced by sepsis. Two cases were reported by Legg, in 1874, which were his first clinical observation, and in 1876 the same author published a case of congenital deficiency of the hepatic and cystic ducts with interlobular and intralobular cirrhosis of the liver. Reference is also made to the monograph of Charcot and Gombault published in 1876 in which the following classification is set forth: Hypertrophic, or Hanot's cirrhosis, cirrhosis depending upon biliary obstruction (the two conditions being identical from an anatomic standpoint), and Laennec's atrophic cirrhosis. The report of 4 cases of cirrhosis following biliary obstruction also appears in the monograph. The cases collected by Manglesdorff, of Leipzig, up to 1882, of cirrhosis depending upon biliary obstruction, numbered 184. In an analysis of the cases collected by Ford he concludes that the most common cause is a congenital deficiency of the bile-ducts. As etiologic factors, gallstones are next in order of frequency. Round, sharp edged stones are much more liable to cause inflammatory changes of the biliary passages than smooth, round stones, and therefore secondary sclerotic changes with stenosis in the ducts follow. Cancer of the head of the pancreas and enlarged glands at the hilus of the liver are rare causative factors. In the early stages the livers in cases of obstructive cirrhosis are large, heavy, very firm, the surface is rough, the biliary passages are dilated and new islands of connective tissue are visible. In the later stages in a large proportion of cases, from the contraction of the new fibrous tissues, the organ becomes smaller, portal obstruction develops (ascites, edema of the extremities, the caput medusæ) and the conditions resemble more nearly the cirrhosis of Laennec. Histologically there is an increase in the amount of fibrous tissues which may be interlobular, intralobular or pericellular and is found around the dilated bile-ducts and the bloodvessels. Many new-formed bile-ducts are also present. This reduplication of the bile-ducts, however, is found in many other pathological conditions of the liver. Ford calls attention to a wreath-like distribution of bile-ducts which has not been previously emphasized except in the cases studied in Montreal, and he therefore suggests that this change may be of importance in determining histologically this form of cirrhosis. From a study of the clinical symptoms, the cases of obstructive cirrhosis reveal a symptom-complex and subsequent changes which are very characteristic. The onset is sudden, marked by extreme jaundice and manifestations of cholemia, clay-colored stools, enlargement of the liver, absence of fever (only being present in those cases presenting intermittent jaundice), emaciation, and progressive loss of strength. Hepatic incompetence and autointoxication is suggested instead of the term cholemia. Later in the course of the disease, when obstruction of the liver is present, symptoms of portal obstruction arise which differentiate this from the ordinary cirrhosis of the liver in which jaundice is present. From an etiologic standpoint he concludes that experimentally cirrhosis of the liver can be produced by obstruction of the flow of bile. In man, however, there is always some degree of inflammation of the bile-ducts and round-cell infiltration accompanying cirrhosis, so that damming back of the bile does not only lead to cirrhosis but may also lead to some degree of inflammatory changes in the bile-ducts. Granting that the bile causes poisonous action on the liver-cells as to cause cirrhosis, yet we are still in doubt as to the route the bile traverses in order to come in contact with the liver-cells. Is it direct or is the bile first taken up by the lymphatic system and circulation before coming in contact with the cells? Three varieties of biliary cirrhosis have been described. 1. The biliary cirrhosis of children in India, which is characterized by painless enlargement of the liver and enlargement of the spleen, great thirst, fever, jaundice, increased appetite alternating with anorexia, constipation and later ascites. Anatomically the liver is bile-stained, typically cirrhotic, and microscopically presents the increase of the bile-ducts, degeneration of some of the liver cells and an abundance

of fibrous connective tissue, which is interlobular and intralobular, often surrounding small groups of liver cells so that it is really pericellular. 2. Hanot's cirrhosis is characterized by attacks of abdominal pain, a dull pain in the region of the liver, increasing jaundice, without clay-colored stools, no ascites or enlargement of the abdominal veins. Emaciation is slow and bodily strength and fair health is maintained for a long while. Enlargement of the liver progresses, and fever, which is at first slight, may become marked and intermittent. The course of the disease is usually chronic, although there are acute cases. Anatomically the liver presents symmetric enlargement, is smooth, does not show perihepatitis, is jaundiced, and the common and hepatic ducts are not dilated or obstructed. Upon microscopic examination the new formed fibrous tissue is both intralobular and interlobular, perhaps more often pericellular. There are inflammatory changes in and about the bile-ducts. 3. Cirrhosis due to biliary obstruction. He gives the important difference between Hanot's cirrhosis and obstructive biliary cirrhosis in a differential table. [F. J. K.]

6.—Sheldon reports a case of **dorsal dislocation of the trapezoid**, which the author states is the second one reported since Gay's case in 1869. The patient delivered a blow with his fist in such a manner that the whole force of the blow was brought to bear on the distal end of the metacarpal bone of the index finger. When the blow was struck there was slight flexion of the wrist and elbow-joint. Patient suffered considerable pain. Upon examination a swelling of considerable hardness was seen that extended about a centimeter beyond the dorsal surfaces of the other carpal bones. There was no crepitus, extravasation of blood, widening of the wrist, or shortening of the metacarpal bones of the index finger. The fluoroscope showed dorsal displacement of the trapezoid. Experiments upon the cadaver, with application of force similar to that causing the injury in the case reported, was tried by the author on 12 occasions. In no case was it possible to produce an uncomplicated dorsal dislocation of the trapezoid, but the result was either that the metacarpal bone of the index finger was fractured or the ligaments were torn, rendering the application of the force in the desired direction futile. It was found upon examination of the anatomy of the parts that division of the dorsal ligaments between the trapezoid and the metacarpal bone of the index finger rendered it possible to experimentally simulate the dislocation. [M. R. D.]

3. A Report of 187 Cases of Measles with Reference to Koplik's Spots and Their Value in Diagnosis. JOHN J. COTTER.
4. Poisoning by Vapo-Cresolene. S. S. ADAMS.
5. Fatal Intestinal Hemorrhage Without Known Cause in an Infant of Five Months. MAURICE OSTHEIMER.

1.—See PHILADELPHIA MEDICAL JOURNAL, Vol. V, p. 1284.

2.—Hereditry is of etiologic importance in the study of tuberculosis, but it has lost its prestige as compared to its former standing. In the light of modern scientific inquiry infection has supplanted direct hereditry as the etiologic factor par excellence in tuberculosis. It is not disputed but that direct hereditry is responsible for a limited number of cases. The great majority of cases of **pulmonary tuberculosis in infants and children**, however, are due to infection. This is proven by the fact that the disease does not appear until the child is at least 3 months old, and, according to the studies of Comby, there is a steady increase of tuberculous cases from 9% during the first year to 38% during the second year. Tuberculosis evidently starts more frequently in the thorax than elsewhere. The infection is not necessarily through the respiratory tract, for the infection may come from the intestines and find its way through the lymphatics to the lungs. Milk is undoubtedly a source of infection, and while not having as vulnerable point of vantage in the intestine of a healthy infant, yet let disease or fatigue lessen the

resistance of the child and infection is possible. The work of Gehrman and Evans demonstrates conclusively that the milk from cows showing the tuberculin reaction should not be used, neither should butter made from such milk be used. In infants we find comparatively few complications; but in patients more than 2 years old complications commence to appear. Of these, tuberculous meningitis is the most conspicuous and severe, while tuberculous diseases of the joints and bones occupy a conspicuous place clinically. The infant of tuberculous parentage should receive proper care from the date of its birth. The nursing should at once become the subject for artificial feeding; the infant should not live in the room with its mother; and kissing should be prohibited. The babe should live in the open air as much as possible; should have a large airy nursery; and should have the surroundings conducive to good living thrown about it. The diet, we know, must be supervised; the milk must be under inspection and should be sterilized. Among medicines, creosote and creosotal have been used with value to the patient. [J.M.S.]

3.—Cotter's studies furnish data concerning Koplik's spots from the complete records of 187 cases. In these cases Koplik's spots were positive 169 times, negative 8 times and doubtful 10 times. Poorly nourished children of the type known as marasmic, those affected with rickets, or with the taint of hereditary or acquired syphilis seem not to present the spots at all, or at least not so clearly as their more vigorous companions. Two patients, a healthy, nursing child, 5 months old, and a vigorous boy of 3 years, did not show the spots. After the discovery of these spots, any attempted methods of restraint did not arrest the progress of the disease, so that we can but believe that when measles reaches the stage of Koplik's spots the exposure to other children has been great. Of the entire 187 cases, not a single one presented Koplik's spots as the only evidence of the disease which was to follow. The author was unable to isolate a single case on the strength of the spots alone, because the two symptoms, fever and spots, invariably traveled together. [J.M.S.]

4.—See PHILADELPHIA MEDICAL JOURNAL, Vol. V, p. 1000.

5.—Ostheimer reports the case of a boy who at his birth weighed 7½ pounds. He did not thrive during the first 3 weeks, his weight falling to 5½ pounds. Then his temperature rose to 101° F., with vomiting and diarrhea. His mother meanwhile died of sepsis. Upon a modified milk mixture the weight of the patient reached 9 pounds. At 4½ months his temperature suddenly rose to 102°. Suddenly, one morning there was a hemorrhage of 8 ounces of bright blood from the bowels, followed by collapse, this was followed by another 8 ounce hemorrhage 2 hours later, and 8 hours after that, 6 more ounces of blood were passed. The autopsy showed no evidence of gross ulceration from which the hemorrhages could have taken place. There were no signs of syphilis nor of tuberculosis. [J.M.S.]

1. Points of Practical Interest in Surgical Gynecology. VI. The Indications for the Operations of Hysterectomy and Myohysterectomy in Myoma. H. MACNAUGHTON JONES.
2. The General Care of the Skin, Considered from the Point of View of Prophylaxis. W. ALLAN JAMIESON.
3. Dental Caries as a Factor of Disease. J. R. LEESON.
4. Observations Relating to the Symptoms and Effects of Oxygen Inhalation. G. LEEB DU TOIT.
5. Notes on Surgery of the Joints. ARTHUR NEVE.

1.—Jones makes a distinction between the terms **hysterectomy** and **myohysterectomy**. By the former he refers to the operation of the complete removal of the uterus, with or without the adnexa, whether by the abdominal or vaginal route, or by what is known as the combined method; by the latter he means the incomplete removal of the uterus, inasmuch as more or less of the cervix uteri is left and the operation is completed without opening the vagina, and hence is termed the supravaginal method. The changes that may arise from the presence of a myoma which would indicate one or another of these operations he classifies

as follows: (a) Degenerative changes in the tumor, which may be mucoid, colloid, calcareous, sarcomatous, suppurative, gangrenous, necrobiotic, telangiectatic, and adenocarcinomatous. (b) Adnexal complications: inflammatory, adhesive, suppurative, and cystic or solid tumors. (c) Bowel complications: obstruction and adhesions, omental or intestinal. (d) Peritoneal complications: peritonitis, pelvic or general and acute, subacute or septic, and ascites. (e) Vesical, renal and ureteral complications: Displacement of the bladder and ureters, adhesions, obstruction of the ureter, hydronephrosis, pyonephrosis, and albuminuria. (f) Circulatory complications: Hemorrhage, anemia and cardiac complications. (g) Those arising from pregnancy: Abortion, miscarriage, ectopic gestation, rupture of the uterus, malpresentation, dystocia, obstructed labor, and postpartum hemorrhage. (h) Mental effects: The disorder of mentalization may vary in degree, from the neurasthenic or hysteric state to phases of melancholia, dementia, or mania. (i) General consequences: Under this he includes such consequences of pressure as difficulty in walking; inflammatory changes in the tumor due to exposure or traumatism; interference with health, consequent upon pain, weight of the tumor, constipation, urinary disturbance, and the depression and apprehension caused by the presence of the tumor. Such examples as inversion of the uterus and actual rotation of the tumor must not be forgotten, although they are very rare. [W.A.D.]

2.—Jamieson discusses the best method of caring for the skin and its appendages with especial view to prophylaxis. He advocates the frequent bathing in cold water and believes in the use of the flesh-brush rather than soap, the habitual use of which he deprecates. He does not believe that warm baths should be taken often. The hair should be washed frequently in cold water. He advocates the use of almond oil, as a lubricant when the scalp is dry, and advises its modification, as may be indicated, with eucalyptus or resorcin. He recommends finally Haegler's method for rendering the hands surgically clean, as far as possible. The surface fat should be removed with a paste of kaolin smeared over the hand for a few minutes; or as Jamieson recommends the use of a paste of emol-keleet instead of kaolin. The hands are then washed with infusion of bran and tincture of green soap, and dried with brisk rubbing with a rough towel. This treatment is radical, and after the operation efforts should be made to restore the natural fat with infusion of bran and lanolin or some other unguent. [T.L.C.]

3.—Leeson advises the routine examination of the teeth and hygienic care of them, drawing attention to cases in which various persistent neuralgias, etc., had yielded when the teeth were properly cared for. He sounds a note of caution lest this simple method of procedure be overlooked in our routine examinations as to the etiology of vague conditions. [T.L.C.]

4.—Du Toit gives his observations relating to the symptoms and effects of oxygen inhalation. He mentions its remarkable hypnotic influence in many cases and states that it has no apparent effect on the respiratory system. On digestion it has the effect of drying the mucous membranes. This is relieved by a draught of acidulated water. It increases the appetite and thus assists the patient gaining weight; he also claims for the gas an antipyretic action. He furnishes a résumé of the various modes of applying the gas to the different parts of the body. He is especially favorably impressed with the routine administration of oxygen in pneumonia, believing that the gas does good by reducing the high temperature and greatly easing the embarrassed respirations. In the treatment of ulcers and wounds he follows Reid in recommending that surgical dressings be not placed on the wound but on a light wire cage or support, which while permitting them to afford protection, prevents them from acting as foreign bodies. The application of oxygen can thus be facilitated to such wounds. Upon the administration of oxygen, the skin around the ulcer or injured portion becomes very dry and it is recommended that lanolin be applied to prevent the skin from cracking. In the treatment of ulcers the patients have the gas applied for several hours at a time, day and night, after having had a sterilized water dressing applied at other times, he reports in general very favorable results of oxygen in cases in which he has used it. [T.L.C.]

5.—In the past 10 years there have been 140 joint opera-

tions done at the Kashmir Mission Hospital. Of this number only 28 were amputations for disease of large joints. He refers to the relative infrequency of amputation since the introduction of antiseptics and quotes figures to confirm this. Of the cases operated on 97 were arthrotomies, with 2 deaths; 30 arthrectomies, with 2 deaths; 70 excisions, with 4 deaths; 343 other operations about joints, with no deaths. Indications for arthrectomy and for excision differ for different joints, the elbow, for instance, requiring excision for a condition, albeit in the knee joint, would only require arthrectomy. In order to preserve function it is necessary to operate before the tissues have been destroyed by disease and the muscles atrophied. Little time should be lost in drainage and rest, with general treatment, unless there is a local and constitutional response. Mortality for the 540 cases was 1.5%; for the major cases, 4%. Of the 28 cases of amputation for diseased joints 2 died. [J. H. G.]

British Gynecological Journal.

1. The Gynecologic Treatment of the Insane. ERNEST HALL.
2. Pregnancy Complicated by a Fibroid Tumor. GEORGE E. KEITH.

1.—Hall gives a comprehensive summary of the subject of the **gynecologic treatment of the insane**, and as a result of his investigations he concludes as follows: 1. The prevalence of disease of the pelvic organs, and the absence of any other determinable organic disease, in many patients who manifest psychic abnormality, coupled with the fact that in a by no means small percentage of cases the removal of the pelvic disease is followed by a rapid return to the normal mental condition, justly lead us to the conclusion that between pelvic diseases and mental aberration there exists some correlation, but as to its exact definition we cannot yet speak. 2. In all cases of mental abnormality in either sex which develops from the advent of puberty onwards, the condition of the pelvic organs, with their functions, should be made a matter of searching inquiry. 3. Whenever possible before commitment in the hospital for the insane, the pelvic organs should be examined, and if any abnormal condition be found, such condition should receive appropriate treatment. 4. That gynecologic treatment should be recognized as a most important part of asylum therapeutics.

2.—Keith reports a most interesting case of pregnancy complicated by a fibroid tumor which was followed by an attack of phlegmasia dolens and pleurisy. The patient subsequently made a satisfactory recovery.

4. The Role of the Fixed Cells in Inflammation. P. BAUMGARTEN.
5. The Physiology and Pathology of Bile-secretion. ALBU.
6. Experimental Bence Jones Albumosuria. ZUELZER.

1.—The causes of **artificial sleep** under the influence of **hypnotics and anesthetics** are not understood. The anemia theory has not been proved. The latest hypothesis is the one based upon the presumed movability of the processes of ganglion cells of the nervous system. Ether, morphin, and other substances, are supposed to arrest the protoplasmic movements and to render the cells unamenable to internal and external stimuli. [D. R.]

2.—The author endorses Neumann's method (Verhandlungen der physiol. Gesellschaft, 1899) of performing the **phenylhydrazin test**. It consists in the use of a solution of sodium acetate in acetic acid of from 50 to 75% strength, or in glacial acetic acid. A special test-tube is employed, the urine is introduced, and the solution of sodium

acetate in acetic acid and 2 or 3 drops of pure phenylhydrazin are added. The whole is boiled down to a certain point indicated by a mark on the tube, rapidly cooled in running water, boiled once more, and again cooled. If sugar is present the characteristic phenylglucosazon crystals appear. [D. R.]

3.—Oil clysters were found by Koch to influence metabolism favorably, in that they increased the absorption of nitrogen and fat, while at the same time the fat introduced into the rectum was in part absorbed and aided nutrition. [D. R.]

4.—Baumgarten reviews the subject of the **role of the fixed cells in inflammation**. He believes that they play an important, if not a cardinal part, and constitute the **primary point of attack** of the inflammatory irritant, and that upon their changes depend the various phenomena of inflammation. The inflammatory irritant may act directly upon the leukocytes (chemotaxis), but the emigration of these cells does not occur through a normal, but through an altered vessel wall. The inflammatory proliferation of the fixed cells is to be looked upon as a reaction of the living cells to the damaging influence of the irritant. No satisfactory **theory of inflammation**, in the present state of our knowledge, can be given. The teleologic view maintained by Marchand, Buchner, Metschnikoff, and others, Baumgarten rejects, on the ground that the effects of inflammation are usually either directly or remotely harmful to the system. He defines **inflammation** as a pathologic process of the tissues produced by mechanic, chemic, thermic, and parasitic irritants, and constituted by alterations of the circulation and nutrition of the tissues, on the one hand, and the reaction of the surviving cells against the irritant and its harmful effects, on the other. [D. R.]

5.—Albu has had the unusual opportunity of observing a patient with a **biliary fistula** that had lasted for 9 years; it was probably the result of cholelithiasis. He was able to study the bile chemically, and also the influence of cholagogues and of diet. It seemed that **fats increased the flow of bile**. Regarding the so called **cholagogues**, he found that none had any value in increasing the secretion of bile. Calomel and Carlsbad waters produce an increased flow of bile by causing intestinal peristalsis and simultaneously a stronger contraction of the bile passages; in that way they bring about an opening of the sphincter of the common duct and a freer flow of bile, but they do not cause an increased manufacture of bile. [Albu says that the use of cholagogues has no physiologic reason to justify it. It seems to us that remedies having the power of increasing the flow of bile, even though it be bile already manufactured, are not to be despised, and have a distinct utility.] The share taken by the bile in digestion was also studied, and here, too, the author comes to iconoclastic conclusions. There was no lessening in the splitting up of fats, and there was also an abundant fat absorption. The utilization of the proteids in the intestines was also unimpaired. The **antiseptic action** of the bile is entirely denied by Albu. In the fistula patient studied, and in another case of complete closure of the common duct by a pancreatic cancer, there was no particularly offensive odor to the feces. Bile itself on standing, quickly becomes putrid. If decomposition were active in cases in which the bile does not enter the intestines, it would manifest itself by an increase in the ethereal sulfates in the urine. These were carefully studied, and no such increase was found. He concludes, therefore, that the traditional view of the antiseptic action of bile in the intestine must be abandoned. [D. R.]

6.—In a dog poisoned with **pyrodin**, Zuelzer found **Bence-Jones' albumose** in the urine. The reactions were with nitric acid a heavy precipitate in the cold, soluble by heat; the same reactions were obtained by the use of sulfosalicylic acid, picric acid, Almén's reagent, acetic acid, and potassium ferrocyanid. A half saturation with sodium chlorid gave a dense turbidity. On heating the urine; acidulated with acetic acid to within 50 or 60° C. a marked turbidity developed, which disappeared on heating to 100° C. The alcoholic precipitate from the urine gave Millon's, the biuret, and the lead sulfid reactions, and in solution the same reactions as the original urine. **Bence-Jones' albumosuria** has been found especially in diseases of the bones, particularly those characterized by progressive anemia. Such an anemia was present in the dog. This suggests an

examination of the urine in grave anemias for Bence-Jones' body. [D.R.]

6. The Application of the Milk Thermophor. P. SOMMERFELD.

1.—The author states that every organ is necessary for the maintenance of health, and that, as self evident as this expression may seem, it, nevertheless, has only been recognized recently, and is even still doubted by some. In discussing the metabolism concerned in internal secretion, attention is called to the fact that there are many organs possessing glandular structure, but no excretory passage, as the suprarenal capsules, thyroid, the hypophysis, the glandula carotica, and the specialized glands of some hibernating vertebrates. From the relation that metabolism has to the blood it is evident that when any species of cell functionates abnormally that there must also be some changes in the blood, and consequently also in the functional activity of other organs, depending upon the pathologic changes that have been produced. The relations between the thyroid gland, suprarenal capsules, pancreas, pituitary body and generative organs and the economy are discussed, and the various results following extirpation of these organs described. [M.R.D.]

2.—The first indication in the treatment of all bronchial processes is the removal of the pathologic exudate eliminated by the bronchi. He believes that expectorants are followed by the reproduction of the exudate. Gravity and altered alveolar expiratory pressure play a minor role. The therapeutic effect desired is not only to alleviate the expectoration but also to regulate it. As soon as the secretion has reached such a level that it encroaches upon the area of still sensitive mucous membrane, expectoration results. This accounts for elimination of the exudate by expectoration when the patient arises in the morning, who, during the sleep, had the exudate evenly distributed through the dilated bronchi with the admission of air into the peripheral portions of various bronchial twigs and thence into the alveoli. The procedure mentioned in the title is indicated in **chronic bronchial blennorrhoea** in consequence of a diffuse, small, cylindric bronchiectasis, and can also be fruitful of good results in **chronic abscesses** of the lungs and sacculated bronchiectasis. Contraindications are all **acute** bronchial affections and **exceptionally large abscess cavities**. [M.R.D.]

4.—Turk believes that there are 2 methods for extracting splinters from the eye. The methods, however, are not to be differentiated by the size of the magnet that is employed (respectively the large magnet by Haab and the small magnet by Hirschberg) or the relative number of experiments, but by the **operative procedure** that is employed. He believes that the small magnet, which in the majority of cases must necessarily be introduced into the vitreous and cause injury to various tissues of the eye, is inferior to the large magnet which even upon external application generally exerts sufficient force to withdraw the splinter out of the wound it originally produced, or to conduct it to the anterior portion of the eye so that a simple corneal section will be sufficient to render its extraction easy. Formerly the indications for the employment of either one of the magnets has been upon former clinical experiments. The author, however, has made a series of experiments regarding the attractive power of the two magnets upon splinters of a given weight and at given distances. In the cases of the large magnets the current employed was from 1 to 18 amperes and in the small magnet from $3\frac{1}{2}$ to $4\frac{1}{2}$ amperes. The results of the author's experiments are as follows: **The small magnet is preferable** when it can be approached within a few millimeters of the splinter without injury to the vitreous. This includes those foreign bodies in the anterior chamber,

posterior chamber, iris or lens which can easily be reached by a corneal section. In more deeply situated foreign bodies where the small magnet can only avail after penetrating the vitreous, the application of the large magnet is indicated. The stronger magnet when properly applied is not only the more effective but also the least dangerous. [M.R.D.]

6.—The advantage of the milk thermophor is to preserve and prepare the milk for some time at a comparatively high temperature, thus obviating the necessity of warming the milk, and with the advantage of always having drinkable milk at hand. Formerly, as established by Frügge, milk that had been pasteurized had to be kept at a low temperature until used. Experiments show that the tubercle-bacilli were killed in the milk that had been left in the thermophor for 4 hours, and that many typhoid-bacilli were killed as well. He sums up the results of his experiments as follows: Milk after being in the thermophor for 4 hours contains but very few germs (sometimes none at all) and typhoid and tubercle-bacilli are certainly killed during that time of sterilization. 18.—In almost every case of **purulent osteitis of the skull**, the dura was sooner or later involved. The character of the inflammation of the dura was either one of the following forms: 1. Gangrene of the dura in connection with gangrene of the brain substance. 2. Extradural abscess; this form being much more frequently found. 3. A diffuse pachymeningitis. This third form was either an acute internal hemorrhagic pachymeningitis, or perhaps a diffuse purulent pachymeningitis. In cases of gangrene the dura was collapsed, black-brown in color, empty of blood, and very foul smelling, and when grasped by forceps, small leather-like pieces were broken off easily. In the purulent pachymeningitis, the dura was red, swollen and soft, and sometimes studded with small hemorrhagic dots; microscopic examination showed small round-cell infiltrations. Clinically it was impossible to recognize when gangrene had set in, and sometimes the extradural abscess was also most difficult of recognition. Chief among the indications pointing toward abscess, was the presence of fever accompanied by gastric disturbances, weakness, diarrhea, and enlargement of the spleen. These symptoms were generally accompanied by the usual signs of cerebral pressure. The pulse was generally quickened. The diffuse form of purulent pachymeningitis caused death very quickly. The prognosis however, of traumatic purulent pachymeningitis is not absolutely fatal, providing proper operation be instituted early enough. In osteitic leptomenigitis, the infection gains access to the pia either from the extension of an extradural abscess inwards or directly from the diseased bone itself. Generally the process is one that might be termed "contact infection." The suppuration penetrates the whole thickness of the dura, and finds its way into the capillary network of the arachnoid, more rarely the suppurative process remains external to the dura, and in these cases leptomenigitis rarely occurs. Sometimes inflammation of the sinus develops before the leptomenigitis, and then the infection gains access to the pia by following along the smaller veins. Simple leptomenigitis rarely occurs, it usually being associated with some complication, such as cerebral abscess or sinus phlebitis. Clinically we recognize two different forms of inflammation of the pia, the circumscribed purulent leptomenigitis or abscess of the pia, and the diffuse leptomenigitis. The second form is again divided into leptomenigitis serosa, purulent menigitis of the cortex, and third,

purulent leptomeningitis of the spine. The prognosis of all forms of leptomeningitis is very unfavorable. [G.B.W.]

19.—Rose reports an interesting case in which the pregnant uterus was displaced forwards so as to appear as a **hernia in the anterior vaginal wall**. The patient was a married woman, 38 years of age. She complained greatly of dysuria and constipation. Examination showed a hard tumor presenting in the anterior vaginal wall, and which apparently pressed the uterus upwards and backwards. Further examination under chloroform was made, and the tumor was supposed to be a myoma in the anterior wall of the uterus. Operation for its removal was made through an incision reaching from the umbilicus to the symphysis. Even after the abdomen had been opened and the hand had explored the tumor, the diagnosis of myoma was still adhered to. An incision in the left tube, however, was followed by a stream of blood, which showed that the diagnosis was not correct. After the tumor had been brought up out of the pelvis, it became much softer, and aspiration withdrew only clear serum; and also by ballotment a body was felt to strike against the palpating finger. The diagnosis of pregnancy was then made and the abdomen immediately closed. About two months later, during an attack of tonsillitis and influenza, the patient aborted, and a fetus about the length of a finger was discharged. [G.B.W.]

20.—Miller has written an elaborate article on **post-operative dilation of the stomach**, brought about through compression of the duodenum by the superior mesenteric artery. In conclusion he says that incarceration of the duodenum by the superior mesenteric artery after abdominal operation occurs quite frequently, only it is not diagnosed as such, because in the majority of cases a cure is brought about either spontaneously or through washing out of the stomach. The condition is generally supposed to be a severe postoperative vomiting, resulting as the effects of the narcotic. He does not mean to say, however, that chloroform-vomiting never occurs, and that every case of post-operative vomiting is the result of intestinal incarceration, but one should bear in mind when dealing with cases of severe and continued vomiting after operation, the possibility of the presence of a duodenum incarceration, and of a consequent dilation of the stomach. Also, at postmortems, in a large number of cases, the cause of death has been put down to peritonitis, whereas in truth the fatal result has been due to the above form of intestinal obstruction.

21.—Tietze has made quite an elaborate research in the **pathogenesis of cystadenoma mammae**. He finds two forms of cystadenoma: 1. the cystadenoma of Schimmelbusch, characterized by an overdevelopment of the epithelium until the alveoli are completely filled by the production of papillary projections of epithelium, with or without connective tissue and by the formation of villi containing glandular acini. This form readily develops into carcinoma. 2. The cystadenoma intracanalicular. This form is characterized by numerous small growths proceeding from the cyst-wall and consisting of a mass of glandular acini. The pedicle of the growth may be penetrated by the epithelium. This form may develop into true adenoma or into adenocarcinoma destruens. The transition form and the true adenoma may be further characterized by a peculiar network of villous-like projections covered by epithelium. Tietze prefers, however, to call both the first and second forms under the simple name *cystoma mammae*, as he believes they are genetically the same. *Cystoma mammae* is generally due to a peculiar inflammatory condition of the breast, leading to the development of multiple cysts, which are characterized by an excessive growth of glandular epithelium seen either in the formation of alveoli and acini or in the form of multiple papillary excrescences, which lead to the development of conditions very similar to that of intracanalicular adenoma. Through the growth of the cyst, the epithelium lining the cyst wall may become flattened out, or entirely lost. A participation of the connective tissue in the inflammatory process is often present, but it is of less importance than the overgrowth of the epithelium. The disease has a tendency to become malignant, either developing into ordinary carcinoma or into the adenocystoma destruens. The tendency of the condition to develop into either cancer or adenoma depends on how far the growth of the epithelium keeps to its normal proclivities of proliferation. [G.B.W.]

22.—Konitzer reviews the literature on **multiple echi-**

nococcus of the liver, but in none of the cases reported can he find any one case in which there were more than 3 cysts present. He, however, reports one from his own experience, in which 5 separate cysts existed in a woman 24 years of age. The cysts were arranged in 2 groups, separated from each other by intervening liver parenchyma. The first group was situated on the left part of the liver and consisted of 2 cysts. These were opened though a laparotomy and drained. The remaining 3 were opened through the pleura and emptied. At the same time a subphrenic abscess was opened. Exudative pleuritis followed the incision into the pleura, necessitating resection a rib and drainage. The patient was finally discharged cured. The first group of cysts was easily approached, because one of the cysts projected just below the sternum. The second group, however, occupied the upper right-hand part of the liver and was hidden under the ribs. The individual cysts of both groups were connected with each other, but no connection could be found between the 2 groups. The contents of the cysts consisted of thin pus containing numerous daughter cysts and bits of membrane. For the development of these separate groups of cysts it is necessary for a double infection to take place, as there could not be found the slightest trace of any connection between the 2 groups. As regards the frequency of occurrence of multiple echinococcus, Konitzer says that the multiple form occurs in about 12 and $\frac{5}{100}$ % of hepatic echinococcus of the liver. The diagnosis of the condition is very difficult, even at the time of operation. [G.B.W.]

23.—Heinricius reports the only case of **retroperitoneal lipoma** which has been put on record in Finland. The patient was a woman, 39 years of age. The growth had been present not over half a year, but at examination the circumference of the abdomen at the umbilicus had already reached 80 cm. The condition was such as led to a diagnosis of abdominal tumor, but the nature of the growth was not determined until the operation. The abdomen was opened in the linea alba, and a tumor projected covered by thin peritoneum, of a yellowish-red color. The peritoneum over the tumor was split longitudinally, and the lower portion of the growth shelled out of its position. The growth was found to consist of 6 lobes, each about the size of an ostrich egg. The upper part of the tumor, which was about twice the size of a man's head, was also removed. The removal of the growth left a large space in the abdominal cavity, surrounded by folds of peritoneum. This peritoneum was stitched to the abdominal wound, and the hole packed with iodoform and sterile gauze. Two months after the operation there was a small unimportant granulating surface present when the patient left the hospital. Heinricius reports quite in detail all those cases of retroperitoneal lipoma which he can find recorded in medical literature. [G.B.W.]

24.—Tenderich reports a case of **intestinal occlusion** occurring in a woman in the latter months of **pregnancy**. The symptoms led to a diagnosis of ileus with the seat of constriction probably just to the left and below the umbilicus. Operation was performed under chloroform, and on opening the abdomen, the markedly dilated loops of the intestine forced themselves out of the opening and were only with difficulty pushed back into the abdominal cavity again. Occlusion was found to be due to a strand of membrane, which ran from the region of Poupart's ligament upwards to above the navel. The part of the intestine which was constricted appeared to have lost its vitality, consequently it was brought up to the wound and left exposed there. The second day after the operation, the patient still having fecal vomiting, the dressing was removed and the suspected portion of the intestine was found to be completely necrosed. The intestine was then sutured in place, and an anus praeternaturalis was made. The patient then made a gradual recovery, though fecal fistula still existed even after the patient had returned to her work. The opening, however, was rendered tight by a Dupuytren's apparatus. 3. Pneumothorax with Valve Mechanism. DUPLANT.
4. Precocious Spinal Syphilis with the Syndrome of Brown-Séquard. BROUSSE and ARDIN DELTEIL.

1.—Guillain reports the case of a woman, aged 52 years, without hereditary antecedents, who had always been in good health except for an attack of variola at the age of 10 years, who complained of icterus. The jaundice began suddenly 7 years before the author saw her, and had been present, with varying intensity, ever since. During the 7 years, crises of splenic and hepatic pain had manifested themselves. At the time of admission to hospital the patient had slight hypertrophy of the liver, an enormous spleen, and icterus. Except for some slight disturbance of the digestion the patient was healthy. Examination of the urine, made at various times while the patient was under observation, showed the presence of biliary pigments but no biliary acids; in a further development of the case the normal biliary pigments disappeared from the urine but urobilin and its chromogen which had existed from the beginning of the case persisted. The patient died after about 8 weeks' residence in hospital after hemorrhage from the nose, the stomach, and the bowels. At autopsy no ascitic fluid was found in the peritoneal cavity. The liver was seen with its sharp inferior border extending well into the left hypochondriac region. The spleen, which was covered above the liver, appeared voluminous and extended almost to the crest of the ilium. Both the liver and spleen were covered with a thick, resistant, whitish false membrane. Examination of the pancreas showed relative hypertrophy of the organ, a hypertrophy that seemed to be principally in the neighborhood of the head of the gland. Microscopically, the liver showed that it was the seat of a portobiliary cirrhosis and presented the lesions of grave icterus. The spleen presented a very dense sclerosis of its capsule, a sclerosis that was rich in fibers, but poor in nuclei. The substance of the organ was also the seat of a sclerosis, but the process was not so dense as it was on the free surface. The pancreas was the seat of an histologic sclerosis that explained its macroscopic hypertrophy. The sclerosis was diffuse and more marked in the lobules than in the spaces between the lobules, so that islands of glandular cells were surrounded by sclerotic tissue. The kidneys showed the lesions of a terminal infection. The case, therefore, was one of **hypertrophy of the pancreas with histologic sclerosis accompanying sclerosis of the liver and hypersplenomegaly.** [J.M.S.]

2.—In a man who had always been in good health, the following symptoms developed gradually: The neck increased in volume, the face became congested and bloated, the thoracic wall became the seat of a hard edema, varicosities appeared at the base of the thorax and extended thence toward its upper portion and its lateral aspect. The upper extremities were edematous and cyanosed. At the same time the patient began to have retrocostal and scapular pains, vertigo, attacks of suffocation, dysphagia, and dysphonia, but no palpitation of the heart. The vesicular murmur was heard all over the right side of the chest; a soft blowing was heard both during inspiration and during expiration in the neighborhood of the right bronchus; the vibrations were absent at the apex on the same side; and at the right of the first piece of the sternum, in the neighborhood of a swelling on the chest-wall, simple pulsations could be seen that were expansile and isochronous with the pulse. There was neither murmur nor thrill; the radial pulses were equal and synchronous, and there was marked tachycardia. Radiographic examination confirmed the opinion drawn from the clinical facts that the condition was one of **aortic aneurysm** that involved the ascending and part of the transverse portions of the arch. The development of this aneurysm by **compression of the superior vena cava**, the right bronchus, the right pneumogastric nerve, and the left recurrent laryngeal nerve, accounted for all the symptoms. Dopter believes that the aneurysm was probably of syphilitic origin. [J.M.S.]

3.—Duplant compares bronchopleural fistulae to the valve in the pneumatic tires of bicycles. Coughing dilates the fistulous tract and fills the pleural cavity, just as the pump fills the bicycle tire. He believes that nearly all cases of **pneumothorax** possess a **valve mechanism**, at least

at a certain period of their evolution. He records 2 cases which show that the pneumothorax of tuberculous patients is sometimes partial at the beginning. The existence of fibrillary adhesions in the serous membrane can alone explain the progressive extension of the gas in the thoracic cavity. These adhesions, therefore, do not constitute an obstacle to the production of a pleural perforation, although they limit temporarily the filling of the serous cavity with air. Rupture of the serous membrane is never seen when there is a total or partial symphysis of the layers of the pleura, but old solid strings that have in some cases undergone an advanced organization are almost always found in the neighborhood of the perforation. These bands immobilize a point of the pleura, while the neighboring region, strongly pulled upon by an attack of coughing, ruptures, particularly if it is rendered more fragile by the presence of a subpleural tubercle or a small cavity. Usually then a bronchocavernous fistula is transformed into a bronchopleural fistula. The frequency of adhesions in tuberculous subjects explains why the majority of cases of pneumothorax occurring in tuberculous subjects are at first partial or multilocular. The lung then does not retract completely from the beginning, it is necessary that the air shall rupture the adhesions in the membranes, as in subcutaneous emphysema it dissects the meshes of the loose connective tissue. The majority of cases of tuberculous pneumothorax in which there is a bronchopleural fistula act as do the cases of pneumothorax with a valve. But the mechanism of the obturation of the fistula during normal respiration ought not to functionate only after the complete retraction of the lung accompanied by absolute immobilization of the thoracic wall and the diaphragm of the affected side. The existence of a membranous valve forming a clapper and closing the pleural orifice is exceptional. In order to cure a pneumothorax with a valve it is necessary to secure the cicatrization of the serous orifice of the fistula. [J.M.S.]

4.—In the case of a man, aged 42 years, who entered the hospital complaining of paralysis of the left leg, Brousse and Ardin-Delteil obtained a history of chancre, which had developed 6 months previously. The paralysis began with pain in the lumbar region, which became worse in a few hours; this was followed by the involuntary passage of urine, and 2 days later the patient found that his left leg was paralyzed. In both legs there was a well-marked hyperesthesia which extended out to the abdominal wall, nearly as far as the umbilicus. There was a painful area in the neighborhood of the spinous process of the third lumbar vertebra. There was incontinence of feces. Under treatment anesthesia developed in the right leg, but the symptoms in general were ameliorated, although they did not completely disappear. After several months the **syndrome of Brown-Séquard** persisted. The case is one of **early spinal syphilis.** [J.M.S.]

1. Trophic Disorders and Disorders of Sensation in Hemiplegics. P. CHATIN.
2. Spasmodic Paraplegia and Sclerosis in Placques of a Family Type. R. CESTAN and G. GUILLAIN.
3. Simple Persistence of the Ductus Arteriosus. G. GÉRARD.

1.—The study of physiology as well as that of pathology leads the observer to the conclusion that the trophic functions of the nervous system are intimately associated with the sensory functions. Chatin has studied the relations between these two functions as seen in cases of **hemiplegia**. Short abstracts of 19 cases of hemiplegia are given. Of these patients 11 presented trophic or vasomotor troubles and 10 of these presented actual **sensory difficulties**, while the eleventh patient did not present actual objective sensory disorders. On the other hand, the remaining 8 patients, in whom hemiplegia was observed without trophic troubles, did not present appreciable interference with sensation. It would seem as though these manifestations were more than coincidences and that it is reasonable to conclude that trophic or vasomotor troubles in hemiplegia usually accompany sensory disturbances. The trophic troubles are principally in the nature of amyotrophies. The muscular atrophies predominate in the upper extremity, while in the lower extremity the atrophy is expressed by a slight emaciation.

Again, it is usually noticed that the upper extremity is the one that presents the most marked contracture, so that this condition is usually associated with amyotrophy and with sensory difficulties. Arthritic disorders are most frequently seen in the shoulder. The most common trophic disorder of the skin and its appendages is a peculiar deformity of the nails, which are bent both in the longitudinal and the transverse diameters, but which are not arrested in growth. The skin becomes particularly thin and glossy. Of the vasomotor troubles coldness of the affected members with redness or violet color of the skin is most common; sensations of pricking, hemisweating, and unilateral edema have also been observed. This series of cases seems to establish the fact that slight sensory symptoms may persist in old hemiplegics. The anesthesia is rarely absolute; the hypoesthesia is usually most pronounced in the hand and diminishes as the examination of the forearm and arm progresses. The mucous membranes are usually uninvolved even when there is marked hypoesthesia in the face. The lower extremity always presents much less marked disturbance than the upper extremity. Disorders of thermic sensation present the same topography, but are often better marked than the disorders of the other forms of sensation. There is sometimes a dissociation between the perception of heat and cold. Disorders of the muscular sense, of the stereognostic sense, and sensorial troubles have also been noted. Motor disorders alone, as they mature, are accompanied by dystrophic phenomena, but motor disorders to which sensory disturbances are added have many more chances of being followed by atrophies. In other words, double lesions of the reflex arc are more often accompanied by trophic manifestations than are simple lesions. The author quotes 12 cases taken from the literature that confirm his position, although there are exceptional cases on record. It seems, however, that the examination of the cases of atrophy from central lesion, either organic or hysterical, published up to the present time corroborate the observation of the coexistence of trophic and sensory phenomena. Goldscheider, Marinesco, and Monakow are all of the opinion that muscular atrophy is the result of simultaneous reduction of the sensory functions, on the one hand, and of the motor and the vasomotor functions on the other hand. [J.M.S.]

2.—Cestan and Guillain report 2 instances of **nervous disease** that presented a **family type**. In the first instance a boy, aged 15 years, had noticed, since the age of 8 years, a progressive and pure spasmodic paraplegia that consisted of an exaggeration of the tendon reflexes of the lower extremities, a spinal trepidation, and Babinski's sign. The movements of the arms became a little stiff as the case progressed. There was no trouble in the face, the tongue, or the eyes. The patient's father and his eldest sister presented the same phenomena, which developed in a similar manner. For 3 years the patients had noticed a spasm of the right sternomastoid muscle. This spasm was intermittent and produced several rotations of the head with lateral inclination toward the right per minute. This spasm was the exact picture of spasmodic torticollis. The authors consider the case to be one of **family spasmodic paraplegia**. In a second family there were 10 children, of whom 1 died of meningitis in infancy, 2 were epileptic, and 2 others presented a special form of nervous disease. Of the last 2 patients, 1, a boy 16 years of age, never walked in a normal manner, but his actual disease did not begin until he was 15 years old. The first symptom was a disorder of speech; several months later he began to present a further disorder of gait, which was of the cerebellospasmodic type. The patellar reflexes were exaggerated, Babinski's sign was present, and his feet were of the type of Friedreich. There was slight ataxia in the upper extremities, but the reflexes were normal. The speech resembled that of sclerosis in plaques. Nystagmus was present, the optic discs were slightly discolored, and the visual acuity was much diminished in the left eye. A sister of this patient, 31 years of age, dated her illness from her twentieth year, the initial symptom of which was a disorder of gait. At the age of 22 years disorder of speech began, and Charcot and Debove at that time made the diagnosis of sclerosis in plaques. At the time the patient came under the care of the authors she presented a very accentuated spasmodic gait with an almost absolute impossibility of walking. The reflexes in the legs were exaggerated, Babinski's sign was present, and there were typical Friedreich's feet. There were

intentional tremors in the arms. The speech presented all the characteristics of that of sclerosis in plaques. Nystagmus was present, but there were no lesions at the fundus of the eye. The diagnosis in these cases was considered to be **sclerosis in plaques of a family type**. Before concluding that a given disease is a family form of sclerosis in plaques or a family type of spasmodic paraplegia it is necessary to exclude hereditary syphilis, to inquire into the character of the labor by which the patient was born, and to exclude meningitis in infancy. In order that a disease should be classed as a family disease it is necessary that it should attack without change in form several children in the same generation, that it should begin at about the same age in all the diseased children of that generation; and that it should be independent, clinically, of all external influence, from an acquired affection, or from an accident during intrauterine life. [J.M.S.]

3.—Gérard contributes an exhaustive paper on the **simple persistence of the ductus arteriosus**, which began in the September number and is concluded in the current number. After examining a large number of cases he concludes that the anomaly may be accompanied by many different symptoms. The author had intended to introduce a chapter on the diagnosis of the condition, but has left it out because it is almost impossible to trace out the manifestations of an affection that is so rare and that presents such a wide range of characteristics. The persistence of the ductus arteriosus should not be considered as a clinical entity that should be attached to the cardiopathies, but as an exceptional affection of a vessel of first importance that has failed to pass through its customary evolution. [J.M.S.]

Semaine Médicale.

December 5, 1900.

1. Treatment of Laryngeal Tuberculosis by Intratracheal Injection of Iodoform in Ether. L. VACHER.
2. A Test by Methylene-blue of Amyloid Degeneration of the Kidney. ACHARD and LOEPER.

1.—For some time L. Vacher has been using with success in the treatment of **laryngeal tuberculosis** an intratracheal injection of the following mixture: Ether containing iodoform to saturation, 100 gm.; guaiacol, 5 gm.; eucalyptol, 2 gm.; menthol, 1 gm. Two cubic centimeters or less is injected into the tracheal tissue with none of the expected discomfort. On the contrary, there is simply a quick sensation of heat, scarcely painful, and no spasm following, which disappears after a few strong respirations. The breath for some hours has perceptibly the odor of iodoform and of guaiacol. With this treatment followed judiciously there occurs a lessening of the laryngeal distress and a general improvement in the patient's health. After each injection a laryngoscopic examination reveals the glottis surrounded by tissue filled with the solution of iodoform. [T.H.E.]

2.—Achard and Loeper note the value of the continued elimination by the kidneys of methylene-blue as a test diagnostic of amyloid change when not complicated by sclerotic degeneration. In the cases in question the diagnosis was confirmed by autopsy. When clinically there is persistent albuminuria, unexplained, and accompanied by various symptoms as of previous tubercular infection, or inconstant polyuria with an excess of globulin upon the serin, the indefiniteness of the latter will suggest the value of the test by methylene-blue. [T.H.E.]

Pneumonia.—Perrheim (*Deutsche med. Wochenschrift* October 4, 1900), describes a case in a 14 months-old child which ended fatally, and in which he found cocci which corresponded in all their characteristics to the **meningococcus**. He reviews the literature and finds that meningococci have been previously found in pneumonias, and have apparently caused the pneumonia. They also are more commonly associated with bronchitis, and it should be remembered that while this bronchitis produced by the meningococcus is usually harmless to the subject and does not tend to produce lesions, it may, perhaps, be the source of further cases of meningococcus infection, and may be the means of spreading epidemics of cerebrospinal meningitis. [D.L.E.]

Original Articles.

ON PERFORATION AND PERFORATIVE PERITONITIS
IN TYPHOID FEVER.*

By WILLIAM OSLER, M.D.,

of Baltimore, Md.

Professor of Medicine, Johns Hopkins University.

CULLEN's remark that the chief function of a physician was to obviate the tendency to death, sounds trite and commonplace in dealing with a condition such as perforation of the bowel in typhoid fever, which is not a tendency to, but, to all intents and purposes, death itself. Until within a comparatively few years, in the presence of this disastrous event, we folded our hands and murmured that all was over. The astonishing results obtained in acute peritonitis from other causes made thoughtful men ask themselves whether something could not be done in the perforative peritonitis of typhoid fever. To two physicians we owe the ardent advocacy of operation—to Leyden in Germany, and to J. C. Wilson in this country. Many of you who listen to me can recall the skepticism so freely expressed, by no one more strongly than by myself, as to the practicability of the procedure; but the surgeons, particularly of this country, took up the question with zeal and energy, and the collected statistics of Keen and of Finney show a most gratifying percentage of recoveries.

I am sorry that we cannot, as a profession, congratulate ourselves upon a reduction in the incidence of typhoid fever in this country. Its widespread prevalence is Nature's judgment upon the transgression of the plain, everyday precepts which we have been preaching in deaf ears for two generations. We can congratulate ourselves, however, upon a striking reduction in the mortality from the disease, for which better nursing and better methods of treatment are responsible. We save 5, 6, or even 7% more patients than we did 20 years ago. We may take $7\frac{1}{2}\%$ as the minimum typhoid death-rate for general hospitals, a figure which should include all cases admitted with the diagnosis of typhoid fever, but from which the doubtful cases of febricula, the estivoautumnal malaria, and cases admitted with the late sequelae of the disease are carefully excluded. It is interesting to note the special class of fatal cases which has been influenced by the modern nonmedicinal methods of treatment. It is not the complications, as hemorrhage, pneumonia, perforation, etc., but it is the largest group in which the patients die of the toxemia. Among 100 fatal cases, 50 die of the progressive asthenia, 30 of perforation, and 20 of other complications. Of 63 deaths in the first 10 years of the work at the Johns Hopkins Hospital, nearly $\frac{1}{3}$ were due to perforation. There has been no material change in the percentage of cases with perforation, as given in Fitz's collection of statistics. Among the fatal cases the relative proportion due to perforation has become higher, owing, as I have said, to the striking reduction in the deaths in the toxemic group.

It is a wonder that perforation does not occur more frequently when we consider the extent and character of the necrotic processes. As the lower 18 inches of the ileum are chiefly involved, the perforation is usually within this distance of the valve. The higher in the bowel, the more likely is the perforation to be in a

small ulcer without much infiltration or necrosis of the walls. The position of the terminal loops of the ileum make the first symptoms of perforation hypogastric, and may give to the case a pelvic or an appendicular aspect. A majority of the cases occur early in the third week; the earlier the perforation the greater will be the difficulties in dealing with the bowel. The earlier the perforation, and the closer to the valve, so much the greater risk of a widespread necrosis of the mucosa and a condition of the gut most unfavorable for any surgical procedure.

In studying the clinical features of these cases one is profoundly impressed, first, with their uncertainty and variability, and, secondly, with the necessity (in view of recent surgical events) of a revision in our methods of dealing with these cases on the medical side. The accident may be divided into two stages: First, the perforation itself; and, secondly, the consecutive peritonitis. The all-important question is to recognize the perforation, and, if possible, to operate within the first 12 hours, before there is widespread general peritonitis. Let me illustrate the uncertainty by sketches of three recent cases:

CASE I (No. 32,411)—Edgar G., aged 24, admitted October 11, 1900, having been ill for more than a month. He looked ill, had only moderate fever, but on the second day after admission he began to complain of abdominal pain, and there was a little fulness. The leukocytes were 7,000. On the 15th the abdomen was again slightly distended, the respiratory movements were well seen, there was no pain, no tension. The hepatic flatness reached to the costal margin. For the next three days the slight distention of the abdomen persisted. There was no diarrhea. At 9 A.M. on the 19th he complained of abdominal pain, which was severe enough to make him cry out. The abdomen was somewhat distended, the respiratory movements were well marked, the muscles were held very tense, the liver-dulness was obliterated in the middle line. The leukocytes at 9.15 were 4,000 per ccm. He had been taken out of the bath a little before 9 o'clock, and was still blue and cyanotic. At 11 A.M., when seen by Dr. Fletcher, he felt more comfortable. He had had one exacerbation of abdominal pain since 10 A.M. The respiratory movements were well seen, though slightly limited below the level of the umbilicus. The muscles were slightly rigid, but there was no actual muscle spasm. There were tenderness and pain on pressure in the lower abdomen, most on the right side. Pressure brought on sudden paroxysms of pain. Rectal examination showed no bulging of peritoneum posterior to bladder. The leukocytes were counted every hour between 11.15 and 4.15, and they did not rise above 5,200. At 2.30 the abdomen was considerably distended, the tenderness in the hypogastric region was marked, but he complained of less pain. At 2.45 P.M. he had a profuse perspiration. The pulse was of good volume and good tension, 92 to the minute. The abdominal muscles were a little more rigid. At 4.30 the patient was seen by Drs. Fletcher, McCrae and Mitchell in consultation. The pulse was still of good volume, but had increased slightly, and he had hiccupped once or twice. There had been no nausea and no vomiting. There was still marked tenderness in the lower abdominal region. Pressure caused the patient to wince. The muscle rigidity was slightly greater over the right rectus. During the day the point of greatest tenderness had varied. There was no actual muscle-spasm. There was slight shifting dulness in the flanks. The liver flatness was not obliterated. There was no increase in respiration, but the respiratory movements were more limited below the level of the umbilicus. The following symptoms suggested the possibility of perforation: The sudden onset of pain at 9 A.M., the persistence of the pain through the day, its association with marked tenderness on deep pressure, the moderate muscle rigidity, the gradually increasing distention during the day, the suggestive movable dulness in the flanks. The following important symptoms so often present were absent: No drop in temperature, no special increase in the rapidity of the pulse, no symptoms of collapse, no nausea

* Read at the Philadelphia County Medical Society, January 9, 1901.

or vomiting, no obliteration of the hepatic dulness, absence of muscle-spasm, absence of any marked diminution of the abdominal respiratory movements, absence of any leukocytosis. It was decided to give the patient the benefit of the doubt.

I saw him at 5.30 P.M. His general condition was excellent, there was moderate distention of the abdomen, the respiratory movements were present, but were relatively much more above the navel, the tension of the abdominal walls was of moderate grade, both iliac fossae were soft and elastic, no spot more painful than another; slight general tenderness. Four finger's breadth of liver-flatness were present just outside the parasternal line. There was no collapse. He was being prepared for operation, and a little excited, and the pulse was 112.

To speak frankly, in this case I had much more confidence in the judgment of my two assistants, Drs. Fitcher and McCrae, than in the symptoms presented by the patient. The sudden onset of pain, the subsequent occurrence of pain in paroxysms, the tenderness, the slight increasing distention of the abdomen were the sole features which warranted an exploration.

Dr. Mitchell operated at 6 P.M., exactly 9 hours after the onset of the pain. The general peritoneum was reddened, but there was no lymph, and it was not until the coils towards the pelvis were lifted up that a perforation was seen, through which feces were oozing. He did very well until the evening of the 21st, when his temperature began to rise, reaching 105° on the 22d, when he died, more apparently from the effects of the fever than from the peritonitis. The abdominal symptoms improved after the operation, and at the autopsy the wound on the bowel was healing per primam.

CASE II (No. 32,765).—The patient had been admitted on November 10, 1900, from West Virginia, about the beginning of the second week of a very severe attack. On November 15, the fourteenth day, he had a hemorrhage from the bowels at 9.30 P.M. At 10.30 he complained of very severe pain in the abdomen, with which he groaned out loudly. At 10.45 the abdomen was flat, almost scaphoid, the respiratory movements were slight, there was no tenderness, no rigidity, no muscle spasm; the leukocytes were 7,500. Throughout the 16th his temperature rose, reaching nearly to 106°. He had some hiccough through the night and in the morning; no vomiting. He was pale and tremulous. The right half of the umbilical region and the right iliac fossa were slightly tender on deep pressure, and the muscles were a little more rigid than last night. There was no definite muscle-spasm. A very important point, on which we did not put enough stress, was the fact that the hepatic flatness, which reached to the costal margin at 11 P.M., at 11 A.M. was 8½ cm. above the costal margin. There was no obliteration in the midaxillary line. The leukocytes rose through the day, and at 12.15 P.M. were 17,500. I saw the patient at 6 P.M., and, considering that he had had a severe hemorrhage, I thought his condition fairly good. The temperature was a little above 104°; the pulse was of fair volume, about 120; the tongue was dry, the abdomen was not distended, the respiratory movements were present, there was slight tenderness on deep pressure. In the nipple line the area of liver-dulness was obliterated. Throughout the evening the patient grew worse, the abdomen became distended, respiratory movements were absent, the abdominal walls became rigid, and there was general muscle-spasm, and the patient complained of a good deal of abdominal pain. He had frequent hiccough, and the pulse rose to 140. At 10.15 P.M. he had a profuse hemorrhage, and though his condition was desperate, it was decided to operate, which was done by Dr. Finney. Gas was escaping from the peritoneal cavity, and there was a bloody exudate with fecal matter in the pelvis. About 12 cm. from the cecum there was a large gangrenous ulcer, which presented two perforations. In the neighborhood of the perforations the walls of the gut were so swollen and infiltrated that a suture would not hold, and before anything could be done the patient died on the table.

In this case, no doubt the perforation occurred on the night of the 15th, but we attributed his symptoms to the hemorrhage, which occurred at the same time. There was an absence of any definite ab-

dominal changes until nearly 24 hours later. A third point of interest, which should have made us suspect perforation earlier, was the fact that at 11 A.M. on the 16th, without abdominal distention, the liver-dulness reached a point 8½ cm. above the costal border.

CASE III (No. 32,925) is still more interesting from the standpoint of the study of the symptoms of onset of perforation. This was a child, aged 8 years, admitted on November 22, on the fifth day of the disease. She had a severe attack, the temperature rising to between 104° and 105°. An interesting feature was that the day after admission she began to complain of pain in the right half of the abdomen, and continued to complain until the 28th. The abdomen was a little full. After November 30, the pain was very much diminished. On the morning of December 5, Dr. McCrae made a note that her general condition was good, the abdomen was somewhat full, everywhere soft, nowhere tender. The leukocytes were 5,500. At 7.15 P.M. she cried out with abdominal pain in the right iliac fossa. The pulse was small, dicrotic, and rapid. The abdomen was a little more distended. She was given turpentine stupes, and after each one she would get quieter and fall asleep. At 11 P.M. there was marked general rigidity of the abdominal muscles, no definite local tenderness. The respiratory movements were fairly free, though perhaps a little limited below the navel. The liver flatness extended to a point 3 cm. above the costal margin in the nipple line. At 11.40 P.M. the leukocytes, which had been 11,500 at 7.30, were 7,500. At 1 A.M. the abdominal pain persisted, and at times the patient cried out with its intensity. The pulse was 150; she had not vomited; the abdominal distention had not increased. The tenderness was marked, and the slightest pressure caused her to cry out. The respiratory movements were less marked than 2 hours before. There was marked rigidity, and definite muscle-spasm. The liver-dulness was completely obliterated in the nipple line. There was slight movable dulness in both flanks, but the value of this sign was diminished by the fact that the patient had diarrhea. The leukocytes at 1 A.M. were 7,700 per ccm.

Dr. Fitcher made a diagnosis of perforation, and urged operation, which was done at 2.30 A.M. Gas escaped when the peritoneum was opened, with cloudy, yellow, bile-stained fluid, of which there was a good deal in the right iliac fossa, and in the pelvis. The coils of the small intestine were not much distended, were pinkish in color, somewhat injected. The perforation was 10 cm. distant from the cecum, clean, punched out in the middle of a not very prominent ulcer. Golden yellow, bile-stained fluid was escaping through it. The perforation was closed with a pursestring suture, reinforced with 3 mattress sutures of fine silk. The patient stood the operation well, and has made an uneventful recovery.

This patient had had a good deal of pain in the abdomen almost from admission, so that she had been carefully watched, but the character of the pain which came on December 5, was different. It was more severe, it had exacerbations of great severity, which caused the patient to cry out at intervals. The movable dulness in this case was shown at operation to be undoubtedly due to the free fluid in the peritoneal cavity. As nearly as could be judged the perforation took place at 6 P.M., and the operation was begun at 2.30 A.M.

You will agree with me, I think, after hearing the narration of these 3 cases, that the time-honored picture of perforation, with the Hippocratic facies, the feeble running pulse, the profuse sweat, the distended motionless abdomen must be erased, as not a picture of perforation, but of peritonitis, or, better still, a rough draft of death. What we need more than anything at present is a fuller knowledge of the symptoms of perforation, particularly of its onset, apart from those of the consecutive peritonitis. I do not think we are likely to do much with what Dr. Cushing has called the preper-

forative stage. I do not think we can hope frequently to recognize a case so early, but it should be a special duty of hospital physicians hereafter to study with more than usual care the earliest possible symptoms in perforation cases. I have been looking over the records of the 30 cases of perforation in typhoid fever which have occurred to January 1, 1901, in my wards since the opening of Johns Hopkins Hospital, and in doing so I was reminded of the dying prayer of the celebrated Archbishop Ussher, that the Lord would forgive him his sins of commission. In the matter of hospital histories and notes even the best men are apt, in the hurry and press of work, to leave unrecorded many important points for which the arm-chair clinician in revising the history seeks in vain. What is essential in every serious case is the watchful care of a man who will be quick to grasp changes in the patient's condition, and who in such cases is in hourly collusion with his surgical colleague. In large general hospitals with many cases of typhoid fever, suspected cases should be visited at short intervals by a skilled resident physician, and not left to the tender mercies of an inexperienced interne. To leave the diagnosis of perforation to the attending physician is, in too many cases, to sacrifice the life of the patient. In 3 at least of our successful cases it was the prompt action of Dr. Fletcher and Dr. McCrae, and the prompt cooperation of the resident surgeon, that decided the patient's chances.

Perforation occurs as a rule in the more severe cases, and during the height of the disease. The rare cases during convalescence need scarcely be considered. Cases with diarrhea and with tympanites are more liable to this accident. Of our 30 cases 20 had diarrhea, 16 at the time of perforation, 4 had constipation at the time, and in 10 the bowels were regular. In 1 it is not mentioned. There is an interesting group (6 cases) of perforation with hemorrhage. When we remember that a large proportion of all cases of typhoid fever if left alone have no abdominal symptoms—neither diarrhea, pain nor tympanites—it is not difficult for the attendant to keep his mind constantly on the alert for the danger signals.

I have drawn up a schedule of specific instructions to be followed in cases of typhoid fever in which perforation is suspected.

I. Instructions should be specific and definite to the night superintendent and head-nurses, to notify the house-physician of any complaint of abdominal pain by the patient, of hiccough or vomiting, of a special rise of pulse or respiration, of sweating, or of signs of collapse.

II. House-physicians should note the character of the pain. As to (a) *Onset*, whether only an aggravation of slight abdominal pain, such as is common, both with constipation and with diarrhea, or whether it was a sudden, intense pain which caused the patient to call out, and which, though relieved by stupes and ordinary measures, soon recurred in paroxysms and grew worse.

(b) *The locality*, whether diffuse or localized in the hypogastric or right iliac regions; radiation, as to penis. It is to be borne in mind that abdominal pain of a severe character may be associated with an acute pleurisy, with distended bladder, with cholecystitis, and with a packed rectum, or may follow an enema.

III. *State of the abdomen*.—The condition to be noted in writing at once as to the following particulars:

(a) Whether flat, scaphoid or distended. Whether, if distended, it is uniform or chiefly hypogastric.

(b) Respiratory movements, whether present, if uniform and seen both below and above the navel.

(c) Palpation, as to tension and pain, locality and extent, and degree of pressure necessary to elicit; muscle rigidity and spasm, whether present or not, and in which special locality, and noting particularly its absence or presence in the hypogastric region and the right iliac fossa.

(d) Percussion—character of note in front of abdomen and in flanks. Liver-flatness, extent, in middle, nipple, and in mid-axillary lines. Note specifically every third hour. Remember, too, that obliteration may occur in a flat as well as in a distended abdomen. Auscultatory percussion may be helpful.

(e) Auscultation—obliteration of signs of peristalsis; presence of friction.

(f) Examination of rectum, whether tenderness; fullness between rectum and bladder.

(g) Stools—character, frequency, presence of blood or sloughs.

IV. *General condition of patient:*

(a) *Facies*, whether change in expression; risus, slight or marked; pallor; sweating, etc.

(b) *Pulse*, change in rhythm, rate and force.

(c) *Temperature*, whether a drop or not, whether after a tub or not.

(d) *Respiration*, sudden increase, not infrequent, whether shallow, or sighing.

(e) *Sweating*, if subject to during attack; if onset with the pain; whether local or diffuse.

(f) *Vomiting*, whether with onset of pain or not; character of vomiting.

(g) *Hiccough*.

V. *Blood-count*.—Leukocytosis, stationary or rising. May be marked and early. In a majority of cases well followed there is a rise. The constant leukopenia in typhoid fever has to be taken into account. Also a count of the red blood-corpuscles and hemoglobin, as a decided drop might suggest hemorrhage.

It is in the hands of the profession to reduce still further the mortality of typhoid fever. The death-rate of the disease under the most disadvantageous circumstances may be gathered from the shocking experience in the South African campaign, in which, to September, there had been more than 25,000 cases of typhoid fever, with more than 3,000 deaths, 20%. In the Spanish-American campaign there were 20,738 cases of typhoid fever, with a mortality of only 1.580—7.61%. The remarkable prevalence of the disease is illustrated better, perhaps, by the fact that 86.24% of the total deaths during the war were due to this cause.

Under the favorable circumstances with which we are surrounded in this country, and the ease with which patients can be nursed and cared for, the death-rate should reach the lowest possible point. For this blessed consummation one most important preliminary is necessary. Our senior students should receive a practical, first-hand, day by day acquaintance with typhoid fever. Heaven knows there are cases enough and to spare in every city in the Union to provide instruction of this sort. But is it given? I do not mean lectures on typhoid fever, or recitations on typhoid fever. I mean seeing typhoid-fever patients day by day, practically having charge of them, and watching their progress from week to week. This can be done, and this should be done in the case of an all-important disease of this character. The worst indictment ever brought against the

medical schools of this country is contained in the recently issued report by Reed, Vaughan, and Shakespeare on the prevalence of typhoid fever during the Spanish-American War. Shades of W. W. Gerhard and of Austin Flint! The young doctors, to whom were entrusted scores of valuable lives, had practically not got beyond the nosology of Rush. Of the total number of 20,000 cases of typhoid fever, only about 50% were diagnosed by the regimental or hospital surgeons. Some of the statistics are perfectly appalling. Thus in 80 out of 85 cases sent from the Fifth Maryland Regiment to civil hospitals in Baltimore, the diagnosis was changed from malaria to typhoid fever. Of 98 cases sent from the Eighth New York Regiment to New York Hospitals all were recognized as typhoid. A majority of them had been entered under other diagnoses. The authors of the report do not improve matters by the lame apology that the army surgeons probably did better than the average physician of the country in his private practice.

There are many lessons which we all have to learn about typhoid fever, but the one I wish to enforce on this occasion is the necessity of watching carefully in the severe cases for the very first features of perforation, in order that the patient may be given the benefit of operation at the earliest possible moment. In general hospitals it may be feasible in the future to save one-half, at least, of the perforation cases. In the severer cases, as in the second one which I have related, the condition of the bowel is hopeless. In another group, illustrated in the first one, the patients recover from the operation, but die of the effects of the disease itself. But one of the most gratifying circumstances connected with the disease has been the demonstration by the surgeons that there is a third group in which complete and perfect recovery may follow. To January 1 of this year 11 cases of perforation have been operated upon from my wards by Dr. Halsted's associates and assistants, Drs. Finney, Cushing and Mitchell, 5 of which have recovered, a percentage of 45.4. Five additional cases have been operated upon by them with 1 recovery, a total of 16 with 6 recoveries, a percentage of 37.5.

HEMOGLOBINURIA COMPLICATING TYPHOID FEVER.

By JOHN H. MUSSER, M.D.,

of Philadelphia,

Professor of Clinical Medicine, University of Pennsylvania; Physician to the University Hospital, etc.,

AND

ALOYSIUS O. J. KELLY, M.D.,

of Philadelphia,

Instructor in Clinical Medicine, University of Pennsylvania; Assistant Physician to the University Hospital, etc.

(From the Department of Clinical Medicine, Hospital of the University of Pennsylvania.)

ALTHOUGH the symptoms, complications, and sequels of typhoid fever have been well described by a large number of writers, it still seems permissible to add to the already voluminous literature on the subject, the report of a single observation of a rather unusual complication—hemoglobinuria. Reference to the literature indicates that while the occurrence of this complication is by no means unknown, it is exceedingly rare, and it is not commented upon by a number of systematic writers on the subject. Thus no mention of the occurrence of hemoglobinuria as a complication can be found

in the articles on typhoid fever in a number of the recent textbooks on the practice of medicine, such, for instance, as those by Osler, Tyson, Anders, Wood and Fitz, Lyman, Whittaker, Thompson, Flint, Strümpell, Eichhorst; nor in the System of Medicine by Pepper, the American Textbook of Medicine by Pepper, the American Textbook of Practical Medicine by Loomis and Thompson; nor in the textbooks on diagnosis by DaCosta, Leube, and Musser; nor in the Medical Complications and Sequels of Typhoid Fever by Hare. However, in discussing the etiology of hemoglobinuria and noting that it may be provoked by the poison of certain infectious diseases, a number of the above-mentioned writers—Tyson, DaCosta, Wood and Fitz, Anders—casually mention typhoid fever in the list of such provocative infectious diseases.

On the contrary, specific mention of the occurrence of hemoglobinuria as a complication of typhoid fever is made by Brannan (Twentieth Century Practice, xvi, 681), Curschmann (Nothnagel's Specielle Pathologie und Therapie, iii, 177, 1898), and Dreschfeld (Allbutt's System of Medicine, 825, 1896). The last-named author states merely that in some severe cases of typhoid fever hemoglobinuria has been observed, whereas Curschmann states that a true hemoglobinuria accompanied with hemoglobinemia has been observed by him in 2 cases of typhoid fever. In the one case, the hemoglobinuria occurred in the middle of the second week, in the other at the commencement of the third week of the disease. Both cases ended fatally under manifestations of intense intoxication. In addition to the foregoing, there has been found a report of a case by Osler (Johns Hopkins Hospital Reports, v, 311, 1895), and the report of another case by Klemperer (Charité-Annalen, xx, 133, 1895). The last-named writer believed that the etiologic relationship of typhoid fever to hemoglobinuria had not been pointed out prior to his communication.

Doubtless, other cases have been observed, and some of them may have been reported, but the complication seems sufficiently unusual and interesting to merit brief mention of the following case:

Patrick H., aged 21 years, single, a colored laborer, and a native of Pennsylvania, was admitted to the medical wards of the hospital of the University of Pennsylvania, to the service of Dr. Musser, August 30, 1900. The following history was elicited by Dr. Evans, the resident physician: The patient's parents, seven sisters and three brothers are living and well. There is no history of tuberculosis or carcinoma in the antecedents. The patient himself went to school until he was 19 years of age, since which time he has been working as a laborer on the railroad. He uses alcohol and tobacco in moderation. While he thinks that he may have had some of the diseases of childhood, he does not remember that he was ever sick. He had specific urethritis one year ago. He was well until August 27, on which day he experienced a feeling of languor, and complained of headache, loss of appetite, and slight diarrhea. He went to work, however, but was obliged to discontinue on account of the headache. During the evening he felt very hot and drank considerable water to relieve his thirst which was marked. The following day he again attempted to work but was again obliged to discontinue and to take to bed. Since then he has complained of languor, weakness, headache, slight diarrhea, and fever. There has been no nosebleed.

On admission the patient's temperature was 104° F., his pulse-rate 96, his respiration-rate 28. The following are the notes of the physical examination made by Dr. C. Y. White: The patient is a mulatto, 5 feet 9 inches in height, of good bony development and good musculature. He is very soporose, and there is marked subsultus tendinum. The conjunctivae are jaundiced. The movements of the eye-balls are

normal; the pupils are somewhat dilated and react to light and to accommodation. The lips are dry, the teeth good. The tongue is heavily coated, but its movements are normal. The visible mucous membranes are pale. The ears are normal. The neck is short and thick and reveals slight pulsations, but no enlargement of the lymphatic glands. Nor is there any enlargement of any of the other superficial lymphatics. The chest is well formed and of good anteroposterior diameter. There are slight depressions on either side of the clavicles at the outer ends. The pectoral muscles show marked tremors. The pulmonary resonance extends on the right side anteriorly to the sixth rib, posteriorly to the ninth spine; on the left side anteriorly to the third rib, and posteriorly to the ninth spine. The percussion note as well as vocal fremitus are normal on both sides. On auscultation the inspiration and expiration are harsh throughout both lungs. The absolute cardiac dullness extends upward to the third rib where it joins the sternum, to the right as far as the left edge of the sternum, and to the left to the fifth intercostal space slightly outside the midclavicular line, at which point the apex beat is visible and palpable. On auscultation there is splitting of the first sound as well as accentuation of the second sound; all sounds are booming and the heart's action is rapid. The radial pulse is rapid and of poor volume. The liver-dullness extends in the midclavicular line from the lower margin of the sixth rib to one finger's breadth below the costal margin. The splenic dullness extends from the eighth rib to the margin of the ribs and from the posterior to the anterior axillary line. The organ is palpable. There is slight abdominal distention and gurgling in the right iliac fossa.

The urine was turbid and claret-colored or smoky; its specific gravity was 1.035; it was acid in reaction and deposited a heavy sediment; it contained $\frac{1}{2}$ by bulk of albumin by the heat and acid test; there was no sugar. Examination revealed the coloring matter to be hemoglobin. Microscopically there were amorphous urates, granular casts, granular debris, and a few epithelial cells; there were no erythrocytes.

The patient was ordered milk and albumen water (the latter on account of his dislike for milk), a tub-bath every 3 hours if his temperature should be 102.4° F., or higher, and a sponge bath should the temperature be between 100° F. and 102.4° F.

On September 1, the patient's temperature remained persistently between 101° F. and 104.8° F., with the exception of short intervals following each bath. There were marked muscular tremors and the peripheral circulation was poor. As he complained much of the milk which nauseated him, he was ordered more albumen-water. In addition he was given whisky with each bath and $\frac{1}{10}$ of a grain of strychnin every 4 hours. The urine still contained a large amount of blood pigment. The test for biliary coloring matters was negative. The Gruber-Widal reaction was reported positive. Examination of the blood revealed the following: Hemoglobin, 15%; erythrocytes, 1,950,000; leukocytes, 8,960.

On September 2, the patient's condition was unchanged except that his pulse was feeble and dicrotic. The stools were reddish-brown and watery, but revealed no blood. His temperature varied between 103.8° F. and 102° F. Hemoglobinuria persisted.

On September 3, hemoglobinuria was still present. The blood examination was as follows: Hemoglobin, 15%; erythrocytes, 1,900,000; leukocytes, 8,880.

On September 5, the temperature manifested some tendency to descend, being about 103° F., with falls approximating 3° F. with each bath. Hemoglobinuria was still present. The stools were watery and contained some blood-coloring matter. Examination of the blood revealed the following: Hemoglobin, 15%; erythrocytes, 2,430,000; leukocytes, 8,800.

On September 6, the urine was amber-colored, clear, acid in reaction, and its specific gravity was 1.020; it contained a trace of albumin, a few granular casts, a few epithelial cells, but no blood pigment.

On September 7, the blood-count was as follows: Hemoglobin, 18%; erythrocytes, 3,290,000; leukocytes, 11,760. Hemoglobinuria was absent. The highest temperature was 102.6° F.

On September 8, hemoglobinuria was still absent. The patient refused absolutely to take any more milk. To disguise its taste it was ordered peptonized.

On September 12, examination of the blood revealed the following: Hemoglobin, 15%; erythrocytes, 3,300,000; leukocytes, 11,840. Hemoglobinuria had disappeared. The patient's general condition had improved. The highest temperature was 102° F. He was ordered ammoniated citrate of iron.

On September 19 and for some days previously, the patient had been noted to be somewhat irrational, in that he stated that since he had been in the hospital he had been married and had bought a house. His temperature for some days had varied between 99° F. and 100° F.; his pulse, which was somewhat dicrotic, was from 78 to 88 per minute; and his respirations from 18 to 22 per minute. The strychnin was increased from $\frac{1}{10}$ to $\frac{1}{8}$ of a grain, four times a day, and he was given half an ounce of whisky three times a day.

On September 20, the patient's temperature reached normal for the first time. On September 23, the urine was amber colored clear, acid in reaction, and of 1.012 specific gravity; it contained no albumin and no sugar. The microscope revealed only a few leukocytes. His delusions persisted, but on all other matters he was entirely rational. On September 25, examination of the blood revealed: Hemoglobin, 55%; erythrocytes, 2,920,000; leukocytes, 5,229. On September 27, the patient was somewhat uncertain regarding the changes in his domestic affairs. His temperature had been normal for four days. The further progress of the case was uneventful. On October 8, the patient was permitted to get out of bed for the first time and he was given a light special diet. On October 17, he had gained considerable flesh and strength, and he was permitted full house diet. His mental condition seemed good. He would only smile when questioned regarding his supposititious wife and house, and he appeared to regard the entire matter as a joke. On October 23, he was permitted to go home. He was still somewhat below par, but he was gaining rapidly. It is to be regretted that another examination of the blood was not made. In all he had had 47 tub-baths, 53 sponge-baths, and 9 ice-pack.

Aside from the rarity of the complication, the case presents several features of interest. Of these might be mentioned the absence of malaria as an etiologic factor, the association of marked hemoglobinemia, the persistence of the hemoglobinuria, for at least 7 days (August 30 to September 5, inclusive), and the ultimate recovery of the patient. In passing, it is interesting to observe that the use of cold-water baths was attended by good results. This is all the more interesting when we remember that cold is certainly the provoking agent in the causation of some cases of hemoglobinuria, more particularly of the paroxysmal variety. As the patient presented hemoglobinuria when admitted to the hospital, the condition cannot be attributed to the action of cold water. As regards the nature of the complication, there cannot be much doubt that it was an unusual manifestation of the typhoid infection. The majority of the previously-reported cases have been cases of severe infection, and most of them have terminated fatally. The infection in our case, while severe, was not extremely so, unless the hemoglobinuria itself be considered an indication of severity of infection. It is not unreasonable to assume that the patient presented a peculiar blood-idiosyncrasy, in consequence of which his hemoglobin and the red blood-corpuscles were especially susceptible to the deleterious action of the typhoid infection or typhoid toxin.

Havana Health Statistics.—The total number of yellow fever cases in Havana in 1900 was 1,244, and the deaths 310, an average of 24%. In 1899 there were 284 cases and 103 deaths. The deaths from all causes 6,102, the smallest number in 10 years, the average for that period being 10,245. During the year, 24,124 immigrants landed in Cuba, against 16,000 the preceding year. In December, 1900, there were 62 cases of yellow fever and 20 deaths, against 70 cases and 22 deaths in December 1899.

THE CLINICAL USE OF THERMOL IN TYPHOID FEVER AT THE ATLANTIC CITY HOSPITAL, ATLANTIC CITY, N. J.

By A. B. SHIMER, M.D.,
of Atlantic City, N. J.

DURING my service at the Atlantic City Hospital, I had occasion to employ thermol in a series of fever cases. The result was so satisfactory that I felt that my experience should be recorded, being impressed with the almost specific action of thermol in this group of cases, an experience which I feel can be repeated by anyone. The most marked symptom of typhoid fever is the fever, and its characteristic influence is best studied when applying antipyretic remedies. As is so well known, the

abled to give it more careful consideration, and in "fever cases" especially our observations were most accurate and systemized.

Dr. Sylvester J. Goodman, the resident physician, gave especial attention in noting its effects and recording the course of each case. The following 5 cases of typhoid fever, taken at random from our case-book, in which was recorded 32 cases treated by thermol without a death, will give a fair resumé of the number of cases treated, the chart of each being an exact copy of the original. All these cases were certified to by the N. J. State Laboratory at Princeton, N. J.

pyrexia of the disease is of serious consequences, and of itself often leads to such. Hence, in the treatment of a disease, the fever of which is the most marked symptom, especial attention should be given to the cause. The removal of the cause is not readily realized, and therefore the selection of some suitable antipyretic presents itself. In choosing such a remedy, we must seek one which may control those conditions of "fever" by inhibiting heat-production, or by dissipating heat, or both, with the least deleterious effect upon the system. As such, I have found thermol to embody these points most thoroughly. My first use of this drug was in a varied number of cases in private work, and the result was so pleasing, I had no fear or hesitancy to employ it elsewhere. In the wards of the hospital I was en-

pital July 26, suffering with an intense headache, vomiting, chills, and a feeling of general weakness. He had been ailing for 10 days or more. Had nosebleed on several occasions. His bowels were constipated. Had a temperature of 102.6° F. on admission. Tenderness of the right iliac region, with a somewhat enlarged spleen and liver, and a few rose-spots were noted. The headache was most intense, so that his whole complaint was directed to this symptom. Calomel in divided doses, with salol and thermol 0.30, every 3 hours, was the treatment begun, and as the fever responded to this treatment, no other remedies for the fever were given. There were no complications. The case ran a typical course with the convalescence somewhat more rapid than generally noted. The patient was enabled to sit up on the eleventh day of his admission, about the twenty-first to the twenty-fifth day of his illness. As (note the chart here given) the highest temperature was noted on the day of his admission, 102.6, and on the sixth day and eighth day, the fall of

the temperature was below normal. This has been noted by other observers who had used thermol in typhoid or other fevers.

CASE 2.—M. A. P., an American by birth, age 22 years, male, single, white, and followed the occupation of a traveler. This patient also gave a history of being ill for two or more weeks prior to his admission to the hospital. Lost appetite, severe headache, pain in the back and abdomen, occasional vomiting, with constipation alternating with diarrhea, more severe after taking a laxative. This patient was very sick on admission, and almost delirious. His temperature was 104° F. There were numerous specific spots seen all over the abdomen. The spleen was enlarged as well as tender. The liver was also somewhat enlarged. The abdomen was tympanitic and painful to pressure, not only in the iliac region, but over the lower bowel. The tongue was very heavily coated and marked by the teeth, whilst upon the

of typhoid fever. The patient was ill for quite a long period, and on attempt to exercise, fell in the streets, and was brought to the hospital in a collapsed condition. The same symptoms of general malaise, dizziness, anorexia, chilly sensations followed by a fever, headache, insomnia, and constipation. On examination on admission, rose-spots were at once seen, with the enlarged spleen and liver, marked iliac tenderness, and tympanites. Bowels obstinately constipated. He had besides the general symptoms of a typical typhoid, also a dry cough, beginning congestion of the lungs. His pulse was also dicrotic on admission, as seen by Chart 3. The temperature on admission was 104° F. A purgative of calomel was given at once with thermol, 0.30 every 2 or 3 hours; the hypodermatic use of strychnia when needed, and turpentine in the form of an emulsion were the remedies used. As seen by this chart, the temperature immediately fell, and so continued with only one rise on the fifth day

teeth were sordes. The pulse was weak, compressible, and dicrotic, necessitating the prompt use of strychnia hypodermically. The treatment in this case was thermol 0.30 doses every three hours when the temperature was above 101, and reduced to 0.18 when the temperature was below this point. His treatment besides this was symptomatic; for the tympanitic abdomen, enemata of turpentine were given, whilst the turpentine in gram doses was administered in an emulsion. This patient recovered, and with no other symptoms but those met with in a rather severe type of typhoid. During the whole course of the disease no other remedy was used but the thermol for the fever, and as the dose at stated intervals was always sufficient to keep the fever in safe grounds, it was continued. As, note the chart No. 2, twice during the course of the disease, the temperature reached normal. A very happy result for any method of reducing temperature in typhoid.

CASE 3.—J. A. B., male, white, single, age 36 years, occupation that of an actor. This may be termed a walking case

after admission, when it fell to normal and so continued. It is difficult in hospital cases to exactly date the day of the disease from the chart, it would appear that the patient was in the third week of his illness when admitted, and that the thermol acted in the nature of a specific. The effects in Case 3 were truly remarkable, and such instances as these were sufficient to prompt us to use the remedy in many instances.

CASE 4.—Mrs. B. M., age 20, married, and occupation housekeeper. Came to the hospital with a history of feeling sick for the past 5 weeks. Her condition was rather unfavorable. Temperature 102.4° F. Abdomen much enlarged, tympanitic with typical spots, spleen enlarged and tender, marked tenderness in the iliac region. Headache, constipation, dry cough, pupils dilated, face flushed, urine scanty and contained albumin. The same method of treatment was pursued. At first, a calomel purge, and then the exhibition of thermol in 0.30 (5 grain) doses until the normal line of temperature was reached, once in 3 hours. After this

the thermol was given in 0.15 (2½ grains) doses. The other treatment was enemata, with the use of strychnia when indicated. As seen by the chart, the temperature was affected at once, and never rose to the height first noted. This remarkable effect of thermol is noted in every case, and throughout the series of cases so treated we never saw the temperature ever go beyond control.

CASE 5.—A. H., age 21 years, white, single, with no occupation. Had been ailing 10 days before admission to the hospital. He gave the same typical history noted in cases of typhoid. Headache, general malaise, anorexia, constipation alternating with diarrhea, abdominal tenderness with nausea, vomited up till a day or so before his admission, when the symptoms became more marked. Two days previous he had nose-bleeding quite profusely, with a chill. The same occurred on the day previous to and on admission. On examination his tongue was found very heavily coated,

called to the peculiarity of the temperature record, the dissimilarity of each from a typical typhoid temperature. I should add, that in each instance, the diagnosis was verified by bacteriologic tests. Widal's reaction was found in each case, nor was a case pronounced typhoid unless every physical sign was in unison, to be completed by a Widal test. The specific action of thermol is thus proven in case No. 5, where a relapse was noted, or rather where an elevation of the temperature far beyond the normal temperature of that particular case was caused by the irritation of the food, thermol acted specifically in reducing the temperature.

To summarize, thermol is an antipyretic of specific effect. In no case was the heart's action at all im-

with clean edge, but dry. His pulse was very weak and rapid, and dicrotic. His abdomen much swollen and covered with spots. Tenderness over the iliac. Tenderness over the whole abdomen, and especially the lower portions. The spleen enlarged as well as the liver. Persistent dry cough and delirium. The patient was placed under the same course of treatment. Thermol, 0.30 every 3 hours, etc. This case pursued the regular course as noted by the other cases until the eighth day (see Chart No. 5), when the temperature rapidly rose to 105.8 F. Investigation led to the discovery that some kind but injudicious friend had given the patient some fruit, with the result noted. Prompt purgation with enemata, etc., removed this complication, and the progress was regular until perfect recovery. Even at the time of the relapse the same plan of giving thermol was persisted in, and the result showed the wisdom of its course. As the Chart No. 5 shows, the general course of the fever was typical.

In presenting this series of cases, attention is at once

paired, but was apparently strengthened. There was in all cases no greatly decreased amount of urine, nor did the skin become exceptionally dry.

From my observations, noted here as well as in private practice, I believe that the earliest moment thermol is administered, in any case, and especially typhoid, the prompter the results, and the more specific its action.

As an antipyretic, it is harmless, and can be given at any time or in any state, any harmful effect as collapse or the like never being noted.

The mode of administration is 0.30 at intervals of 2, 3 or 4 hours, and to be given when the fever begins to rise; and to be continued even after the fever has disappeared, in smaller doses and at longer intervals. No fear of collapse need be feared. Hence, there is no need of any additional medicine, as whisky or the like.

TWO CASES OF LOCALIZED NEURITIS OCCURRING AS A COMPLICATION OF TYPHOID FEVER.*

By H. J. WHITE, M.D.,

Resident Physician, Samaritan Hospital, Troy, N. Y.

LOCALIZED neuritis is one of the rarer of the many and widely distributed complications of typhoid fever. Multiple neuritis, on the other hand, is much more common. The etiology of the latter condition is now fairly well established, the most generally accepted theory being, that the toxins produced by the typhoid bacillus act directly on the nerve fibers, causing a mild perineuritis. But the singling out of one nerve or set of nerves and the production of a paralysis more or less complete of the muscles supplied by them, must be due to some special individual susceptibility to the effects of the toxin. The first case herewith reported is one of double ulnar neuritis, which is more marked on the right side.

M. C., aged 50, a widower, teamster by occupation, was admitted to the Samaritan Hospital May 31, 1900, and gave the following history: Family history: Father died of paralysis, mother of cancer. No history of tuberculosis in family. Personal history: He has always been very robust until the present illness began. About February 1, 1900, he suffered from headache, which was followed by sore throat and general malaise. His case eventually pursued the usual course of a moderately severe attack of typhoid fever. At the end of 6 weeks he had several attacks of hemoptysis; also, at about this time, he complained of pain at the inner side of each elbow, which radiated downward along the ulnar side of the forearms, and ended in the little and ulnar side of the ring fingers. He described this pain as sharp and shooting in character. Both legs were slightly swollen, and there was muscular tenderness of the calf-muscles. At the end of about 2 weeks the lower extremities had regained their normal condition, but the pain in the arms was still present, although of a milder degree, and the hands re-

FIG. 1.—Showing atrophy of interosseous muscles.

mained stiff and useless. Examination made May 31, 1900: Patient poorly nourished, conjunctivae pale, tongue protrudes straight, no tremor, and is covered with a grayish-white, moist coating. Pupils dilated, respond to light and accommodation. Chest somewhat pigeon-shaped, vocal frem-

itus increased on the left side from the sixth rib downward. Over the same area is bronchial breathing and bronchophony, elsewhere the lungs are normal. The superficial area of cardiac dulness is 7.5 by 6 cm., apex-beat in the fifth space, in nipple-line; at the apex is a soft, blowing, systolic murmur which is not transmitted. Liver and spleen normal. Examination of abdomen negative. Reflexes normal.

FIG. 2.—Showing contractions, and position of hand in ulnar neuritis, post-typhoid.

Urine clear amber color, normal odor, specific gravity 1.020, acid; no albumin or sugar; microscopically urates. Blood: Red cells, 3,440,000; white cells, 6,125; hemoglobin 70%. Repeated examination of the sputum failed to reveal any tubercle-bacilli, and the area of consolidation in the left chest is probably fibroid in type. On the right hand the fingers are all stiff, and complete extension is impossible. The little finger is strongly flexed; the thumb is abducted; and the last phalanx is in a condition of slight flexion. There is marked atrophy of all the interossei muscles. The skin over the little and ulnar side of the ring fingers is smooth and glossy; there is also an absence of hair, and the nails on these fingers present deep furrows. There is anesthesia, analgesia, and thermic anesthesia along the ulnar side of hand, on both sides of the little finger and on the ulnar side of the ring finger. Neither of the motor nerve-points give any response to the faradic current. The left hand presents a condition similar to that of the right, excepting that it is of a much milder type, and the hand has nearly regained its normal condition without contractions.

The patient remained in the hospital until September 15, 1900. Electricity and counterirritation were tried, but the condition remained unchanged.

The second case is one of a still more uncommon condition called the *tender toes of typhoid fever*. This condition was first described by Handford, an English physician, and later by Osler, who considers it to be a form of mild neuritis. He also states that this complication is more common after the cold-bath treatment.

F. G., aged 28, single, a teamster by occupation, was admitted to the Samaritan Hospital September 20, 1900. Family and personal history is entirely negative. He had been complaining of headache, diarrhea, and general malaise for a week previous to admission, but had not been confined to his bed.

Examination, September 21, 1900: Patient is well nourished, tongue protrudes straight, no tremor, thick, dry, grayish-white coating. Pupils normal. Examination

* Read before the Medical Association of Troy and vicinity, November 8, 1900.

of heart and lungs is negative. Spleen percussable and palpable. Tenderness and gurgling in the right iliac fossa. Urine clear amber color, acid, specific gravity 1.032; no albumin or sugar. Diazo reaction positive. Blood: Red cells, 3,440,000; white cells, 6,250; hemoglobin, 80%; Widal reaction positive. This case developed into a severe type of fever, and the patient had in all 15 cold baths. His heart's action became extremely weak, and on October 20 he had an attack of syncope, in which there was no pulse, and the heart-sounds were barely audible. He was deeply cyanosed, rigid, and covered with a profuse perspiration. By means of energetic stimulation he rallied in about half an hour. On October 22, being the thirty-third day of the disease, he complained of severe pain in the tips of the toes of both feet. On examination nothing abnormal could be seen. There was neither redness nor swelling, and no increase of surface temperature. Motion did not increase the pain, but the slightest pressure caused him to cry out. It was necessary to keep the weight of the bedclothing off the feet by means of a bedcradle. There was hyperesthesia and hyperalgesia of the tip and bottom of each of the toes; thermic sense normal; plantar reflexes absent; kneejerks normal. The pain and tenderness continued for ten days and then gradually abated; still, at the end of two weeks, he could scarcely bear the weight of the bedclothes. Examination of the blood, October 28: Red cells 2,990,000; white cells, 6,250; hemoglobin 60%.

In this case, as well as the former, the question of a local inflammatory condition might arise, but the absence of redness, swelling and heat as well as the absence of leukocytosis would entirely exclude that condition.

I am indebted for the privilege of using these cases to the attending physicians (Drs. March and Gardinier) of the Samaritan Hospital, Troy, N. Y.

THE PHENOMENA OF ATROPIN POISONING FOLLOWING THE CESSATION OF THE RESPIRATORY MOVEMENTS.

By EDWARD T. REICHERT, M.D.,

of Philadelphia.

Professor of Physiology in the University of Pennsylvania.

(From the Physiological Laboratory, University of Pennsylvania.)

In a somewhat recent article (*University Medical Magazine*, 1891, vol. iii, p. 207) on certain physiological actions of atropin, I called attention to the vulnerability of the respiratory center towards this poison, and it was shown that even when arterial pressure is reduced almost to zero, owing to the vasomotor paralysis, the heart's action continued strong, and that large doses could still be injected directly into the circulation before the heart succumbed. The sensitiveness of the respiratory center, as I have shown also in the actions of strychnin and brucin, is so great as to render impossible a study of the full complement of its actions on mammals unless artificial respiration is practised. When this is done several times the minimal lethal dose can be injected intravenously, and the animal kept alive for hours, and ultimately recover normal respiratory movements. During this interval some very interesting phenomena are developed.

The intravenous injection of from 0.02 to 0.04 gram of atropin per kilo of body-weight is sufficient to arrest the respiratory movements and thus cause death by asphyxia. If, however, upon the cessation of the respiratory movements artificial respiration be carried on, the respiratory center soon exhibits evidences of recovering activity in the form of feeble, infrequent respiratory movements, which gradually increase in strength

and frequency until complete recovery. When the first dose is soon followed by another, the paralysis of the respiratory center continues for a longer period, and after repeated doses it may exist for hours and yet complete recovery occur. The center exhibits extraordinary recuperative power even after doses many times larger than is necessary to arrest its activity.

A critical study of the details of such experiments, the records of two of which are here embodied, shows that after the cessation of the respiratory movements three periods appear, each having marked characteristics. The *first period* lasts for a variable time, depending upon the dose, and is characterized by tremors, occasional rigid extensions of the body and legs, clonic convulsions, and choreal movements; increased intestinal peristalsis; primary increase and secondary decrease of the pulse-rate; absence of the conjunctival reflex; and very feeble activity of the respiratory center, so weak as to be insufficient, when artificial respiration is stopped, to cause more than a few very shallow respiratory movements. It is a period of waning activity in general, especially of respiratory, vasomotor, thermogenic, and motor functions, the lessening of motor activity being preceded, however, by a transient increase.

The *second period* is also of variable duration, depending upon the dose and other conditions attending the experiments. During this period there is absolute muscular quiet of the skeletal muscles; the conjunctival, patellar and other tendon and skin reflexes and reactions are abolished; the pulse-rate is low, and the arterial pressure at a minimum, both, however, showing finally a decided tendency to recovery; body temperature continues to fall; and the respiratory center is paralyzed, exhibiting absolutely no manifestation of activity even after a permanent stoppage of artificial respiration. This period is one characterized especially by the complete paralysis of the respiratory center; suppression of the conjunctival, patellar and other external reflexes; and a state of absolute quietude of the skeletal muscles.

The *third period* is initiated by slight muscular twitches, which increase in vigor and frequency and pass into jerkings, which in turn become stronger, and after a time violent in character and paroxysmal; walking movements and others of a rhythmic character may be observed; the body temperature may continue falling notwithstanding the marked general recovery of activity; and after a time the respiratory center exhibits signs of a restoration of activity in feeble respiratory movements which steadily become stronger. During this period there is a general waxing of activities, changes which, on the whole, are the reverse of what was observed during the first period, and culminating in the recovery of the functional power of the respiratory center, and the consequent return of effective respiratory movements.

The whole train of effects shows extraordinary power of recovery of the system from the actions of atropin. In one experiment here recorded 1.5 grams of atropin, or over 6 times the minimal lethal dose, were administered in divided doses, yet within 2 hours after the first injection feeble respiratory movements re-appeared—there was a return of reflexes, the pulse-rate was higher than it was immediately after the first injection (with pulse-curves about half as high), and arterial pressure had increased about fourfold. Fifteen minutes later the respiratory movements were sufficiently frequent and

deep to dispense with artificial respiration. In the second experiment 1.6 grams, or over 7 times the minimal fatal dose, were given in divided doses, and the same strong, general tendencies towards recovery were sooner or later manifest.

Certain other actions are also worthy of special note: Intestinal peristalsis was for a time markedly increased, this being in accord with the work of Meuriot, Keuchel, and Ott, and opposed to that of Bezold and Bloebaum, and lends support to the theory that atropin

1 14 20 00		126	46		Very little muscular excitement; pulse curves higher.
1 20 00 00		78	52		Pulsus alternans.
1 30 00 00					Motor and sensory nerves absolutely inexcitable to a strong faradic current, yet strong forced movements occur in all four extremities coincidentally.
1 40 00 00	0.3 (quinin sulph.)	162	80		
1 40 10 00					
1 40 13 00					
1 40 18 00					Forced movements, etc., completely arrested.

Duration of experiment, 1 hour and 40 minutes. Average minimal lethal dose for dog weighing 12,924 kilos, 0.387 grams. Total dose in this experiment, 2.8 grams.

These results in conjunction with the facts set forth in the article referred to in the beginning of this paper show that the respiratory and vasomotor centers are particularly susceptible to atropin, and that both exhibit towards it great powers of recovery.

in small doses excites, and in large doses depresses, the inhibito-motor fibers of the splanchnics.

The effects on the reflexes and tendon reactions are not without interest. The conjunctival reflex disappears, but the patellar reaction may remain. When the

poison is pushed the latter also is suppressed. The absence of one and the presence of the other has been noticed also in nitrous oxid poisoning, and in strychnin paralysis. In curarized animals the patellar reaction is lost before the conjunctival reflex.

The effects of large doses of atropin upon the motor and sensory nerves are very positive, both being completely paralyzed during the second period. A curious fact shown by these experiments is that while the motor fibers are absolutely inexcitable to Faradic stimulus they retain their conductivity. This is evident in the absence of response to strong stimulus when applied to the sciatic nerve, while at the same time rhythmic movements of undoubted central origin occur coincidentally in all four extremities. This associated loss of irritability to Faradic excitation and retention of conductivity has also been observed in dogs to which enormous doses of strychnin or brucin have been administered, and in nerves poisoned with boracic acid, CO_2 , and coniin, and in regenerating nerves.

The motor phenomena exhibit certain features which justify more than a passing mention, especially those of the third period. This period is initiated by gradually developing motor excitement. The slight muscular twitches increase in strength, and finally pass into jerks, and these steadily become more vigorous. The jerks at first lack rhythm, but as the effects of the poison progress they tend to become paroxysmal and to pass into forced movements of a choreal, or of a more or less definitely coordinated character. These forced movements, which, of course, are of centric origin, can be stopped immediately by the intravenous injection of sulphate of quinin. In the foregoing two experiments, 0.24 gram and 0.3 gram, respectively, were sufficient to immediately and completely arrest the motor excitement.

Finally, the results of these experiments with enormous doses of atropin have a very important bearing upon the treatment of poisoning in man. They show clearly that death is due to a paralysis of the respiratory center, that the center has great recuperative power, and that if artificial respiration be properly practised the respiratory center recovers its activity, which is accompanied by general and marked improvement of other depressed states. In man, it seems that atropin poisoning should be readily treated if artificial respiration be persistently and intelligently practised, as by Laborde's method, and accompanied by such other treatment as indications suggest.

REPORT OF A CASE OF CHOLELITHIASIS WITH FORMATION AND RUPTURE OF AN ABSCESS OF THE ABDOMINAL WALL.

By JOHN H. GIBBON, M.D.,

of Philadelphia

Assistant Surgeon to the Jefferson College Hospital; Surgeon to the Out-patient Departments of the Pennsylvania and Children's Hospitals;
Surgeon to the Bryn Mawr Hospital.

THE following case of gallstones is reported because of the interest it holds from a diagnostic and pathologic point of view. I first saw the patient on September 26, 1900, with Dr. E. J. Stout, and she was admitted on that day to the Jefferson College Hospital. The history she gave was as follows:

R. S., a widow, 50 years of age; occupation, housework.

Family History.—Mother and one sister died of apoplexy. Father died suddenly in his eightieth year. Six sisters and one brother living and well. No history of tuberculosis or malignant disease obtainable.

Personal History.—Remembers no illness in her youth. Menses always normal. Never had typhoid fever. For the past 15 years has suffered from dyspepsia.

Present trouble began 4 years ago, when patient had a severe attack of abdominal pain situated in the right side of the abdomen, low down, radiating to the umbilicus and occasionally to the right shoulder. Since this attack patient has had many others, and has never been entirely free from pain in the lower part of the abdomen on the right side. The attacks lasted two or three days, and none were so severe as the first; patient never vomited, and was never jaundiced, never collapsed from pain, and never, so far as she knows, passed any gallstones.

On November 6, 1899, had a severe attack of pain lasting several days, accompanied by chill and fever on the first day, and throughout by headache and constipation, but no vomiting and no jaundice. The point of greatest pain was situated in the right iliac fossa, and the disease was diagnosed appendicitis by her attending physician, a man of ability and large experience. The application of an ice-cap relieved her suffering. Patient recovered from this attack, as from the others, but continued to have a dull, aching pain in the right iliac region.

Dr. Stout first saw the patient about the beginning of the following summer, when she consulted him for advice regarding a mass which was forming apparently in the abdominal wall over the region of the appendix. She did not appear to be very ill and did not see her doctor with any regularity. About the last of August the mass softened and opened, discharging a small quantity of pus and leaving a sinus which has remained open ever since. It is interesting to note that when the patient came to Dr. Stout she was wearing a truss which had been recommended by another physician for the relief of the mass, which was supposed to be a ventral hernia.

On admission, temperature, pulse and respiration, normal. Heart and lungs, normal. Urine, turbid, amber, acid; specific gravity, 1.021; no albumin; no sugar; urea, 1.2; no pus, blood, or tube-casts.

Examination of the abdomen showed a small sinus, $2\frac{1}{2}$ inches internal to the right anterior superior spine of the ilium, and $\frac{3}{4}$ of an inch below the level of this spine. Around the sinus the abdominal wall was indurated, red and tender for a considerable area so much so as to render palpation and percussion of the right side of the abdomen very painful and of no advantage. From the sinus there was discharged a mucopus. A bent probe passed into it could be moved about in what seemed a small, irregular cavity, but it could not be passed to any depth in any direction.

That there was an abscess of the abdominal wall was apparent, but its cause was obscure. The very positive history of attacks of appendicitis and the situation of the sinus exactly over the normal position of the appendix, of course, made us think of the possibility of this organ being the cause of the trouble; but the character of the discharge and the extensive infiltration of the abdominal wall remaining so very long after the opening of the abscess, together with the fact that when rupture did take place there was only a small amount of pus discharged, caused us to put this idea aside and examine in other directions.

The possibility of having to deal with a suppurating cyst suggested itself, and the question of its being a broken-down gumma was also discussed. The gall-bladder never entered my mind, because of the patient's history of never having been jaundiced, of always hav-

ing the pain in the right iliac fossa, of passing no stones after the attacks, together with the diagnosis of appendicitis and the situation of the sinus. The mucous character of the discharge and other facts in the history of the case which were elicited subsequently, should have caused us to consider the gallbladder. I concluded it was an abscess of the abdominal wall and did not think it had any connection with an abdominal viscus. Dr. Stout had already given the patient iodid; but we decided, as she had been very irregular in her treatment, and because of suspicious-looking scars on her legs, to try increasing doses of the iodid and the local application of mercurial ointment.

After about a week it was decided to thoroughly open and curette the abscess.

Operation.—On making an incision I found an abscess dissecting in several directions and containing

about an ounce of pus mixed with a clear, thick fluid. The abscess walls were thick, tough, and smooth. After curetting thoroughly every pocket, I found one in the bottom of the wound that was small and seemed to contain something hard which I could not move. With a hemostat I dilated the pocket and then withdrew, much to my surprise, a gallstone, and following it 51 others. The stones were uniform in size, being a little larger than peas. When I had dilated the opening sufficiently to admit my finger, I found that it went, not into a sinus leading into the gallbladder, as I had expected, but at once into the gallbladder itself; and I was able to pass the end of my finger into a dilated cystic duct, from which I removed several stones. The peritoneal cavity was not opened. A large drainage-tube was inserted and the patient returned to bed. She reacted nicely, her temperature but once going above 99°, and she went home on the twenty-fifth day with the wound practically healed.

During the first week there was a considerable dis-

charge of bile, which showed the cystic duct to be clear of obstruction; and as no jaundice developed after the external fistula closed, we felt sure that the common duct too was free. The fistula closed completely soon after the patient went home, but opened again within a few weeks and discharged bile and mucus until recently, when it closed again and has remained so ever since.

Diagnosis.—The first interesting question which this case suggests is that of diagnosis. Not infrequently there is difficulty in making a differential diagnosis between inflammatory conditions of the gallbladder and the appendix; and the fact that a number of excellent surgeons have reported cases where they operated expecting to find one of these conditions and, to their surprise, have met with the other, makes it a matter of importance. The error of diagnosis, however, I do not think is often made from a want of means or symptoms which would at least suggest a doubt, but, rather, from a tendency to consider only the prominent symptoms and to make a hurried diagnosis. The fact, too, that both the conditions require operation, makes us less careful, and we rest with the idea of making the diagnosis after the abdomen is opened.

In the case I report, however, I think, from the patient's history, that it would have been difficult to make a correct diagnosis of the attack which she had in November, 1899, everything pointing towards the appendix region and practically nothing suggesting the gallbladder. It has been shown that gallstones are much more common than is generally supposed, occurring in from 5 to 10% of autopsies done on Europeans. In a large number of these cases no symptoms were present in life which pointed to the condition. I suppose that no one will doubt, in the light thrown on this case by the operation, that the patient never had appendicitis, but that what was supposed to be this condition was a displaced and inflamed gallbladder, which was probably becoming adherent to the parietal peritoneum over the right iliac fossa. It is, of course, a question whether gallstones were present at this time and whether they might not have resulted from the inflammation, which in its turn was due to the colon-bacillus, it having been proven beyond doubt that this bacillus, or nearly any bacterium, may produce a precipitation of the solids of the bile and the formation of gallstones.¹ It would seem, however, when the previous history is considered, that the gallstones were present at this time and were the cause of the inflammation and suffering. I do not think it would have been possible to make a diagnosis of gallstones when the patient was admitted to the hospital in September of this year; for, besides the absence of symptoms, the inflammation and induration of the abdominal wall rendered examination very unsatisfactory. The character of the discharge should, however, have made us suspect the real condition.

Pathology.—The first thought in regard to the pathology of this case is the abnormal situation of the gallbladder in the right iliac fossa. Enormous distention of the gallbladder is not infrequent, cases having been reported where this condition was mistaken for ovarian cyst. Robson speaks of a specimen in St. Bartholomew's Museum, in which a greatly distended gallbladder formed the contents of a femoral hernia. Carl Beck reported in the *Annals of Surgery* for May, 1899, an in-

¹ Mayo Robson's "Gallbladder and Bile Ducts."

interesting case of transposition of the viscera, in which gallstones developed and were removed through an incision made along the outer border of the left rectus muscle. In my own case it will have been observed that there was practically no distention of the gallbladder and no ptosis of the liver; so its abnormal position must be accounted for in some other way, and I think the correct explanation is a long peritoneal attachment to the liver. Under ordinary circumstances the gallbladder is in intimate relation with the under surface of the liver, being kept in this position partly by the peritoneum, which passes from its sides to the liver; but Brewer (*Annals of Surgery*, June, 1899) in examining 100 bodies, found in 5 that the gallbladder was completely surrounded by peritoneum, which on passing to the liver formed a mesentery which permitted considerable mobility. In three cases there was an extension forward of the free border of the lesser omentum to the fundus of the gallbladder.

Robson reports a case (Case No. 234, p. 281) which in many respects resembles the one here reported: "Strong family history of phthisis; in 12 months several attacks of severe pain in the right iliac region, accompanied by swelling in the normal situation of the cecum, and marked tenderness between anterior superior spine of the ilium and the umbilicus; each attack associated with fever, constipation, vomiting, and abdominal swelling; and all signs of local peritonitis over inflamed appendix. Operation; incision over cecum; viscera matted together by old and recent lymph. After separating adhesions, gallbladder was reached at end of projecting Riedel's lobe; mucopus and several gallstones removed; tumor of cystic duct felt, and as on incision it gave the appearance of growth, it, with the gallbladder and projecting lobe of liver, was removed by means of the elastic ligature." The patient recovered.

Although in a few cases adhesion, ulceration and perforation into stomach or bowel have taken place, yet, probably, in most instances the gallstones produce an empyema which is evident from local and constitutional symptoms. As the organ is usually found in its normal position, adhesion to the pylorus or bowel, or to the liver, is more frequent than to the parietal peritoneum. This being true, the gallstones are much more apt to find their way into these viscera than through the abdominal wall. When adhesion to the parietal peritoneum once takes place, and ulceration and perforation follow, an abscess forms, and the pus usually works its way along in the direction of the umbilicus, where it is apt to open externally. This may not always be true, however, for many cases are reported in which the fistula found its external opening as low down as the symphysis pubis. Adhesion of the ducts, and of the gallbladder itself, to the pylorus and duodenum is frequent, as shown by operations and autopsies, and results often in dilation of the stomach or obstruction of the bowel. Obstruction of the bowel has also been caused by a large stone which has ulcerated into the bowel. Ulceration and perforation into the general peritoneal cavity may take place without the formation of protecting adhesions, as is shown by Case 241 of Robson's series. Robson says that "if the ulceration advances toward the adjoining hollow viscera, stomach, duodenum, or colon, adhesions, as a rule, follow, and the perforation is effected quietly. In one case of this kind—after a history of cholelithiasis, followed by severe stomach symptoms—the gallstones were vomited, and complete recovery followed." Cases have also

been reported where the gallstones have by ulceration made their way into the pleural cavity and the urinary tract. Occasionally an adventitious sac has been found, formed by adhesions of neighboring parts, containing gallstones, and communicating with the gallbladder by a small opening. There is, of course, the constant danger of rupture of such a sac, and the production of a fatal peritonitis. Again, the gallstones have ulcerated into the walls of the ducts, and have remained until removed by the surgeon.

Death from hemorrhage not infrequently follows operations on the gallbladder in cases where there has been a long-standing jaundice, which has produced an aplastic condition of the blood. In these cases death from hemorrhage has followed perforation of the gallbladder. About a year ago I saw death occur from continued and persistent oozing of blood from an incision into a gallbladder which was much inflamed and where the patient had long been jaundiced.

Fistulae.—The question of fistulae, internal or external, after ulceration, and of external fistula after cholecystotomy is of interest. It seems, from postmortem observations, that we must conclude that the fistulae established between the gallbladder and the other hollow viscera tend to become obliterated after a time, and this is apt to be true too of the external fistulae produced by ulceration.

Fistulae following operation are not nearly so frequent as they were before Robson taught us how to avoid them by suturing the gallbladder to the fascia instead of to the skin, as had formerly been the practice. He reports 189 cholecystotomies with 14 fistulae following, but 5 of these occurred in the first 10 cases, where the gallbladder was sutured to the skin. Since modifying the technic he has not had a single fistula where the ducts have been cleared at the time of the operation. A mucous fistula, of course, indicates an obstruction of the cystic duct.

A CASE OF MIRROR-WRITING AND OF DIFFUSE HYPERTROPHY OF BOTH BREASTS IN AN EPILEPTIC NEGRESS.

By W. G. LIST, M.D.

Recent Assistant Physician to the City Hospital, St. Louis, Mo.

MIRROR-WRITING is a striking and uncommon phenomena occasionally observed among feeble-minded or left-handed children. It is specially apt to occur in a patient who has had a right hemiplegia in early life. Mirror-writers use the left hand, and for them the natural way is to write from the right to the left side of the page instead of from left to the right. The letters are reversed and require the aid of a mirror before they can be deciphered. If a word or sentence written by a mirror-writer is held in front of a looking-glass the characters can be easily read in the reflected image. Rotch, in his textbook on pediatrics, describes two cases of mirror-writing, both occurring in negro children of defective mentality who were also subject to convulsions, and he says there is a physiologic tendency for left-handed children to fall into the habit of mirror-writing. According to Dana (*Twentieth Century Practice of Medicine*, Vol. X), mirror-writing is seen in hemiplegics, more commonly in children. A right-handed person who has had a right hemiplegia attempts to write with the left hand and finds that he almost

unconsciously writes from right to left and reverses the letters. The pathology of this condition is unknown. Diffuse hypertrophy of the breast consists of a general hyperplasia of the entire gland. The disease is rare. Billroth, in his Treatise on the Mammary Glands, remarks on the rarity of this condition, having seen but

FIG. 1.—Hypertrophy of breasts.

two cases in his extensive experience. Dennis, System of Surgery, Vol. IV, quotes Williams, who says that while 2,422 cases of mammary neoplasms came consecutively under treatment at Middlesex, University College, Bartholomew's, and St. Thomas' hospitals during a period of from 16 to 21 years, only 6 cases of diffuse hypertrophy were seen in this same period. The cause of the disease is unknown, but it seems to be associated with certain disturbances of the genital organs, especially the menstrual function. The growth is usually very rapid for several months, after which it ceases. The breasts are likely to increase again at pregnancy. This disease occurs more frequently in the negro race. It is said to occur at two periods: first at the age of puberty; second, in connection with pregnancy. The great majority of cases develop at the onset of the menstrual function.

The concurrence of the above-described anomalies, mirror-writing and diffuse hypertrophy of the breasts, were noted in a patient who was admitted to the Ohio Hospital for Epileptics, at Gallipolis, November 4, 1897. The history of the patient is as follows:

Lillie Herst, colored, female, aged 17 years, born in Ohio. She was admitted to the hospital from a county infirmary. Her surroundings in early life were evidently very poor. She possesses a very limited education, the frequency of her epileptic seizures preventing regular attendance at the school conducted for patients. On account of the patient's pronounced imbecile condition no family or previous history

could be obtained from her. She is shy and retiring, of a mild and tractable disposition, with cleanly habits. Her only occupation is that of making beds, which she was taught to do only after a painstaking effort on the part of the attendant. The general health of the patient during her residence at the hospital has been good, excepting several periods of physical depression due to taking bromides. Her epilepsy began at the age of 3 years and has continued irregularly until the present time. Her attacks are of an atypical grand mal type; there is no petit mal. A seizure commences with an aura of impending suffocation, at which time the patient clutches her throat in a violent manner, requiring restraint, which is followed by shrill cries, which continue throughout the convulsive part of the attack, and the stage of stupor which follows is of short duration. She seldom has an attack at night and she never was in status epilepticus. Her menstrual function has not established itself in a normal manner. The first menstrual flow occurred 3 months after admission to the hospital, when the patient was 15 years of age. During the course of the year, 1898, she only menstruated 3 or 4 times at irregular intervals. During the next year she menstruated regularly, the flow was of normal amount, lasting 3 to 4 days, with no unusual physical or nervous depression. She has menstruated but once during the present year. The physical examination discloses the following:

The patient is a paralytic of average size for her age and race. The gait is normal; the mensuration of both lower extremities shows them to be of the same dimensions. The right patellar reflex is slightly exaggerated, but is absent on the left side. She is unable to use the right arm for executing the finer movements; it is slightly atrophied, the corresponding measurements being $8\frac{1}{2}$ and $8\frac{1}{4}$ ccm. for the right and left arms respectively. Considerable ataxia of the right hand still remains. The thoracic and abdominal viscera are normal. When she was admitted her breasts were seen to be a little more enlarged than one would expect to find in a person of her age and physique; after the appearance of the first menstrual flow, the breasts rapidly enlarged, so that within a period of 6 months they attained their present size. During this time she also increased in weight 30 to 40 pounds. In the course of the following year she gradually lost the increased weight, but no decrease in the size of her breasts was noticed. During the period of rapid growth they were slightly painful to touch, their increased weight causing her considerable discomfort. She complained of aching and dragging pains at the insertion of the pedicles of each breast. Both mammae are pendulous, and dilated veins

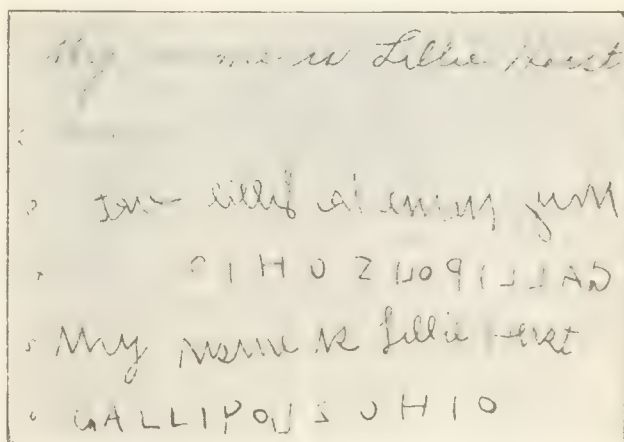

FIG. 2.—Mirror-writing.

are visible at their periphery. The overlying skin is of normal thickness and freely movable. There is no increase of fat, and the lobes of the gland-substance can easily be palpated. There has never been any secretion from either breast. The measurements of each breast are as follows: The right breast is 11 inches in length, in the mamillary line, from the attachment of its pedicle to its lowermost boundary; the left 10 inches. The greatest circumference of the right breast is $11\frac{1}{2}$ inches; left breast, $11\frac{1}{4}$ inches.

The fact that she was a mirror-writer was discovered accidentally. While visiting the cottage wherein the patient resided I noticed her in the act of copying printed words from a book on a slate. All the letters were, however, seen to be in a reversed position as compared with the original copy. When the slate was held in front of a mirror the words could then be easily read in the image. She was given several copies to reproduce, and specimens of her writing are illustrated in Fig. 2. Nos. 1 and 2 are copies she was given, and Nos. 3 and 4 are her efforts at reproduction. Nos. 5 and 6 are reproductions from Nos. 3 and 4, showing them as they appear in a mirror. The patient can copy printed letters more easily than script and can only write a few simple words from dictation. She has been taught to write in the normal manner, but when not on her guard she always begins on the right-hand side of the page and reverses her letters. The left hand is used exclusively in writing.

A Method for Destroying Mosquitos.—In the *Bulletin de Pharm. de Lyon* is recommended a method for the destruction of mosquitos. On account of the well-known properties of these insects in the conveyance of the malarial parasites, a solution of potassium permanganate 1:1500, has been found to be quite effective and cheap. [M.R.D.]

Regarding the Methods of Experimental Investigation, in Determining the Elimination of Hydrochloric Acid in the Human Stomach, upon the Ingestion of Various Nutritive Substances.—W. Bockmann (*Zeitschrift für diet. und physikal. Therapie*, Bd. iv, Heft 5) believes that more accurate results can be obtained by employing the substances used in test-meals, not by weight, but by their caloric values. [M.R.D.]

Dermatitis, Tetanus, Desquamation, and Edema in a Case of Grave Gastrointestinal Autointoxication.—Valeza (*Gazz. degli Ospedani e delle Clin.*, 1900, No. 111) reports a case of gastrointestinal autointoxication in a child causing scarlatiniform inflammation of the skin, tetanus, desquamation and edema, which the author attributes to the influence of the autointoxication upon the nervous system. The observations of Guida and Ponticaccia (*Dispepsia e sistema nervoso*) are discussed. [M.R.D.]

Sarcoma of the Testicle.—Kayser (*Mittheilungen aus den Hamburghischen Staatskrankenanstalten*, Bd. 11) found a history of trauma in 7 cases out of 21. The most predisposing age was that between 30 and 40 years. The beginning of the tumor formation and its further course were almost always painless, and in some cases a hardening of the testicle had existed for years before the presence of a neoplasm could be demonstrated. The condition was generally monolateral and associated with hydrocele. The prognosis was extremely unfavorable; only 2 of the 21 cases have recovered and 16 died from metastases. Secondary involvement occurs not only by the blood-stream but also by the lymphatics, as was seen in 7 cases with associated retroperitoneal lymphatic involvement. The author does not advise operation in the presence of secondary involvement for fear of increasing the latter. [M.R.D.]

Contribution to the Study of the Gonococcus and Its Toxin.—Christmas's (*Annal. de l'Institut Pasteur*, 1900, No. 5) experiments show that the gonococcus, when thriving on a culture medium especially suited for it, eliminates toxic materials, which, when applied in a weak dose to the brain of animals, causes death with characteristic symptoms of poison. The culture medium must be selected with particular care, the best being calves' bouillon, chicken broth, or rabbit broth with some gelatin, to which either rabbit's serum or ascitic fluid, but no peptone, are added. The gonotoxin does not arise from the toxic material of the dead bacteria, but is a biologic product produced only under certain cultural conditions; it can be obtained from a pure culture with a saturated solution of ammonium sulfate. The

subcutaneous injection of this toxin produces an antitoxic material in the blood of the animals experimented upon. [M.R.D.]

The Elimination of Bacteria by the Kidneys and Liver.—Mélin (*Annal. de l'Institut Pasteur*, No. 6), agrees with those authors whose experiments showed that as long as the liver and kidneys are in a normal condition, bacteria will not be eliminated by them. The author injected intravenously into rabbits, bacillus subtilis, pyocyanus, prodigiosus, typhosus, anthracis, and staphylococcus aureus, and the same organisms into the subcutaneous tissue of guinea-pigs. From time to time bacteriologic examinations of the urine were made, the urine having been obtained from the exposed bladder by aspirating through a slough in the bladder-wall so as not to injure bloodvessels. The same precaution was taken when aspirating bile from the gallbladders of animals. Both the urine and bile, when unmixed with blood, never contained the injected bacteria. Mélin believes that these organs only permit the entrance of micro-organisms from the blood into their secretions when their epithelia are the seat of pathologic changes. [M.R.D.]

Induced Labor in Eclampsia.—Ludwig Knapp (*Prager medicinische Wochenschrift*, Vol. 25, No. 51) calls attention to the successful results obtained in eclampsia from induced labor. In 47% of the author's cases the convulsions ceased, and in 23½% the violence of the paroxysms diminished so that, on the whole, 70½% cases of eclampsia were partly or totally relieved by the induction of labor. He quotes Ferri, of Milan, who had a mortality of but 7% in 82 cases of eclampsia in which labor was induced. The author remarks that, "Bossi's dilator is the best instrument for dilating the cervical canal. He describes a case of a primipara, who presented the prodromal symptoms of eclampsia; albumin in the urine; eclamptic convulsions; L. O. A. dilation of the cervix; rupture of the membranes; version and extraction of an almost asphyxiated full-term fetus, which was subsequently rapidly resuscitated. The convulsions ceased after delivery and both mother and child were discharged in 10 days without complications. [M.R.D.]

Regarding the Healing of Injuries Produced upon the Crystalline Lens of the Frog, Fish, and Birds.—Knap (Zeitschrift für Augenheilkunde, vol. III, No. 3 and 6; vol. IV, No. 1; abstracted by Pfister in the *Korrespondenz-Blatt für Schaeffer's Archiv*) in experimenting upon the frog obtained the following conclusion: 1. Even wounds extending deeply into the lens are not followed by traumatic cataract but heal with but very little remaining opacity. 2. The union of the wound in the capsule as well as the filling-up of the disturbed portions of the lens are accomplished by the epithelium derived from the capsule. 3. The clearing-up of the opacity is due to the changes that occur in the cells of the capsule, which ultimately fill up the gap produced by the wound. These changes are an increased transparency of the cells as well as alterations in their shape and position. 4. Every injury to the lens gives rise to the new formation of lens-fibers at the equator, and for this reason the tissue which fills up the wound has a tendency to penetrate deeply. 5. The scar in the capsule is covered at its internal surface by a new normal epithelium, forming a capsular cataract as in the rabbit. 6. Loss of substance in the equatorial region is replaced by new-formed lens fibers. 7. Wounds at the posterior surface of the lens and capsule are closed by "tongue-shaped" cellular elements from the equator, which later on become changed to lens fibers. 8. Injuries situated at the center of the lens may clear up by themselves. 9. By removing the lens and leaving the capsule, a new lens will be formed from the latter. The result of No. 9 was obtained by injuring the lens with a needle so that the whole lens was brought to lie in the anterior chamber. After an almost total opacity of the lens it was absorbed in 2 months, and a newly- but not entirely regularly-formed lens could be demonstrated. The same result was observed in three experimental luxations of the lens. In the fish (goldfish) it was also shown that deep and extensive injuries of the lens did not cause a total cataract but only a superficial and circumscribed opacity. In the bird, although one would expect a total opacity of the lens on account of its soft consistency, such did not take place in spite of the marked traumatism. [M.R.D.]

Recent Studies in Hydrophobia.—The development, segregation, and final grouping together of the individual symptoms as a separate disease, and the search for a pathogenic factor, a distinctive or specific pathology to establish such a grouping of symptoms as a distinct clinical entity on a scientific basis, are well illustrated by the changes which our ideas in regard to hydrophobia are undergoing at the present time. Although the clinical pictures as found in the best books of medicine seemed clear and well defined, there could always be found men of ability who denied, in the absence of a distinctive pathology, the existence of such a disease. Thus, a skepticism had developed in the medical profession in regard to hydrophobia, and one may search in vain the health reports of Philadelphia for a case of hydrophobia. Such a diagnosis is not recognized, and death from this cause may be found under the head of convulsions, etc. At the last meeting of the Pathological Society of Philadelphia, Drs. Ravenel and McCarthy (*University Medical Magazine*, January, 1901) read a paper confirming the work done in Europe during the past year on the pathology, and the diagnosis from the pathological lesions, of hydrophobia. All the material sent to the University was made use of in this work. Van Gehuchten and Nelis had described the essential and distinctive lesions of rabies in the peripheral, sensory, and sympathetic ganglia. The normal intervertebral ganglion, or ganglion on the cerebral nerves, is composed mainly of large ganglion cells; each cell is surrounded by an endothelial capsule of one layer of cells. Between the capsules there is a stroma of connective tissue, nerve-fibers, and bloodvessels. In the ganglion of a rabid dog the cells are degenerated, shrunken, and may have disappeared. In the place of the degenerated and atrophied cells are the capsules filled up with masses of small, irregular, nucleated cells. As the ganglion cell degenerates and shrinks the capsular cells proliferate and fill up the capsule, and, together with a leukocytic infiltration which occurs in the stroma, give a distinctive picture to the section. Other changes are found in the spinal cord and medulla, but they are not so constant or characteristic as the ganglion changes. These changes are not found as a constant pathological factor in any other disease, and only very rarely as an accidental factor, the result of some direct or indirect irritation. These changes occur in practi-

cally all cases of street rabies, and are missing in very few of the cases where the disease is conveyed by subdural injections into rabbits.

The changes above described occur very early in the disease, and have a very practical value as a means of early diagnosis. Much valuable time for treatment has been lost in the past waiting for a positive diagnosis in an animal suspected of rabies, who has bitten several people. At least 14, and often 20 to 30 days was necessary before a positive opinion could be expressed, and an accident to the experimental animal destroyed all evidence for or against the diagnosis. It is now possible to give an opinion within 24 hours of the death of the animal. Prophylactic treatment (Pasteur) may then be instituted immediately with better prospects of success and with lessened possibility of a useless expenditure of time and money. Such was often the case when the animal was destroyed without a positive diagnosis having been made. These investigations will furnish food for thought for those who hold that hydrophobia is a disease of the imagination, a fatal fear, a deadly hysteria; and a feeling of gratification to those who have been struggling for so long a time to establish it as a distinct clinical entity. It is difficult to see how fear or imagination could cause such widespread changes in the central nervous system.

The Absorbable Suture.—Ever since the introduction of antiseptic and aseptic surgery one of the regrets of the surgeon has been that, although his wounds heal primarily, yet not infrequently an early or late accumulation of pus takes place, "breaks," or is opened, and a sinus established, which continues until finally there is discharged or removed from it one or more silk sutures or ligatures. This was a very common occurrence a few years ago and is still not infrequently met with where silk is used to any extent. The suture or ligature which has always seemed the ideal one to the surgeon, is one that would serve its purpose and then be absorbed and not remain a foreign body in the tissues. The dissatisfaction which has always accompanied the use of suture-materials which had to be removed, or which became encysted, and oftentimes, even though perfectly sterile at the time of introduction, produced irritation, inflammation or abscess, with which all surgeons are too familiar, has

caused both the clinician and the laboratory investigators to labor for a suture that would fulfil all the immediate requirements and that would not give rise to postoperative infection. The animal sutures, which are practically the only ones which are absorbed with any certainty in a reasonable time, have been so difficult of sterilization, and consequently so productive of immediate wound-infection, that many surgeons have been slow to accept them in much of their work as a substitute for silk, the sterilization of which is so simple. Repeated and laborious experimentations have, however, been so productive of good results that now, at the close of the past decade, we find the operators in all departments of surgery gradually discarding the nonabsorbable silk and silver wire for the absorbable catgut and kangaroo tendon. The alcohol-bichloride, the cumol and the formalin methods of sterilization of animal sutures have become so perfectly satisfactory, both from a laboratory and practical point of view, that when properly carried out they may be absolutely relied upon. The substitution of catgut, both plain and chromicized, for silk and silver wire has been most marked in the past few years, and even in tissues where silk was thought to be the only possible and safe ligature or suture-material, we find the surgeon now using the absorbable animal suture. Many abdominal surgeons now use catgut entirely as a ligature for even the large pedicles which must be constricted in the pelvis; and in appendicial gallbladder and intestinal surgery it is rapidly finding its way. Probably the one place where silver wire seemed to hold absolute pre-eminence was in the suturing of bone, and yet in this work catgut and kangaroo tendon are finding ardent advocates, who continue to report good results from its use.

In the ligation of small vessels silk may now be said to have no place, and in the closing of wounds, even those of the serous membranes, it is being less and less employed. Though the field for the use of both silk and silver wire is so rapidly contracting, yet these materials will always have their place in surgery. It is certainly true, however, that in the satisfactory sterilization of the animal suture the surgeon has realized one of his ideals.

The British Congress on Tuberculosis.—Probably the most important and widespread disease that afflicts mankind is tuberculosis. We hear so much nowadays of some of the other infectious diseases, such as plague, yellow fever, and malaria, that we are likely to overlook the stupendous mortality from consumption in its various forms. More than 8,000 people die annually from this disease in Pennsylvania alone; while in the United Kingdom of Great Britain and Ireland 60,000 deaths are recorded annually from tuberculosis, and it is stated on good authority that at least three times this number of persons are constantly suffering from one form or other of the disease. Moreover, this ac-

tivity of tuberculosis is constant; year after year it is and has been, and apparently will continue to be, the same devastation over the face of the globe. Plague and yellow fever are rather more dramatic in their onset and progress, but tuberculosis, while it may not appeal so strongly to the imagination, has a worse effect on the death-rate than either of the others.

As an offset to this sombre picture we may record the fact that probably no disease is being made the object of persistent, intelligent, and organized opposition to such an extent as tuberculosis is at the present day. The opposition is even taking on a missionary zeal and evangelical fervor, for the public is being educated by tracts and in some places the pulpit is even giving out a warning cry. Perhaps these popular methods are not always the wisest, but they at least indicate a curious awakening on the subject of consumption. Much more effective will be such an assemblage as the forthcoming British Congress on Tuberculosis. This congress will meet in London in July next, and the prospects are that it will be a most noteworthy gathering. The preliminary program, which lies before us, already maps out wide territories for scientific work. This work will include medical, climatological, pathological, bacteriological, and veterinary tuberculosis, as well as hygiene and state medicine in reference to this disease; and will be illustrated by means of a large museum. It is to be hoped that many of our American specialists will take part in this congress, not only for their own sakes, but especially for the advancement of this work, than which no greater now enlists the sympathies and activities of scientific men.

Scientific Work in Psychiatry.—Dr. Edward N. Brush, physician-in-chief to the Sheppard Asylum, near Baltimore, has discoursed in a very rational and luminous way, in his recent annual report, on the vexed problem of how to get more scientific work done in hospitals for the insane. Dr. Brush, who has had a large experience in the asylums, does not seem to have been enervated by breathing the atmosphere of these much-maligned institutions. He wants more scientific work done in them, while recognizing that there are practical difficulties in the way of converting all our well-ordered asylums into busy hives of clinical and pathological workers. This seems to us to be the first absolutely essential step in the solution of this whole question, *i. e.*, that the asylum men themselves come to recognize the need of more science. This progress must begin from within. It must be spontaneous, not forced from without. Whatever the difficulties may be, there will be found a way to overcome them when those who are most nearly concerned feel the impulse to forge ahead. Whatever the obstacles, only the men on the inside know them well enough to really surmount them. For these reasons we believe that the

one real hopeful sign for the scientific progress of the asylums is in the fact that men like Brush are fully awake to the necessity of bringing the science of psychiatry up to the same plane of activity and fruitfulness that has been attained by the other medical sciences.

Dr. Brush thinks that the failure to secure great results comes from the lack of correlation in the past between laboratory work and clinical work. These two must be better correlated. In this connection we would remind him of Kraepelin's recent recommendation that small psychiatric hospitals be established in connection with teaching clinics. In this country it might be better if more small or medium-sized hospitals were established with a view to having some relation with a near-by clinic and laboratory, so that in effect each would be part of a great teaching plant. One difficulty in this country is the tendency to hypertrophy. Institutions must swell to immense proportions, in order to catch the public eye, if they are to fulfil their proper destinies. This should not be so with all our hospitals. A few well-selected and well-studied cases will give infinitely better results to science than a thousand beds consigned to the oblivion of routine. There is a stimulation that comes from a teaching clinic that cannot be artificially produced anywhere else in the world. It is this stimulation, this contact of young, eager, and inquiring minds, that is lacking in many of our hospitals for the insane. Dr. Brush would tend to solve the problems of psychiatry if he would create a teaching clinic at Sheppard Asylum, or utilize its material for such a clinic.

Erroneous Pharmacy.—In these days when the markets are flooded with all sorts of well-recommended drugs, it is not enough that these preparations be free from the taint of quackery and commercialism. They should all be free from the possibility of doing harm, such as might arise from the mistaken judgment or lack of experience of the well-meaning physician or pharmacist who recommends them to the profession. Dr. William Murrell has just sounded a note of warning, for instance, in reference to one of the new preparations of arsenic, known as the cacodylate of sodium. We are told by its sponsors, who are mostly French physicians, that although this drug contains a large amount of arsenious acid (as high, even, as 55%), it has none of the toxic action of that salt, and that it may be given by mouth, and even hypodermically, in comparatively large doses. Dr. Murrell's experience did not support this claim. He administered one grain of the drug in pill form, and before eleven doses had been taken he observed such well-marked and even alarming symptoms of arsenicism, that he was forced to discontinue its use. A distinct odor of garlic was noted on the breath on the second day, and by the fourth day the patient had been vomiting, and her face was pallid, eyelids edematous, conjunctivae injected, and her tongue pre-

sented the appearance of a piece of raw beef. In addition, and far worse, there was arsenical neuritis in the limbs, marked by loss of power, abolished knee-jerks, and pain in the nerve-trunks on pressure. Arsenic is too virulent a poison, and Dr. William Murrell is too good an authority for us to let his important letter in the *Lancet* (December 29, 1900) go unnoticed. This drug has recently been used in one of the hospitals of Philadelphia with results which, we are credibly informed, indicate that it is a very potent toxic arsenical preparation.

In this connection we would suggest that reputable pharmacists, whose intentions are doubtless of the best, and who, in fact, are often misled by physicians themselves into exploiting some particular medicine, would do well, before launching new preparations of the more poisonous drugs, to have them completely tested on the lower animals. This might wound the feelings of the antivivisectionists, but it would probably save human suffering here and there.

Mosquitoes and Disease.—The search for the pathogenic mosquito still goes on. Having fastened the responsibility for malaria upon this insect, the scientists seem bent upon fixing the blame for yellow fever upon it too. We trust we shall hear something more definite on that point at the coming Pan-American congress in Havana. The rôle of the anopheles in malaria seems to be well established, but we still need more definite information about the completion of the life-cycle of the malarial parasite. Is the mosquito the intermediary host, or is the essential link—"the means by which its existence is assured from year to year"—the individual known in the *Lancet* as "malarial man"? During the past year a few facts of importance—confirmatory rather than truly originating—have been added to our knowledge of the propagation of malaria. Thus Manson's experiment on himself was confirmatory. He submitted himself to be bitten by some imported anopheles mosquitoes, and promptly developed an attack of tertian fever. This was a disease that he could not readily have picked up in England, and the plain inference is that the imported insects gave it to him. Again Drs. Sambon and Low, with Signor Terzi, betook themselves to the most infected spot on the Roman Campagna, and by protecting themselves from the bites of mosquitoes, entirely avoided the disease. Other persons around them, who took no precautions, as promptly took it. The desideratum now is to find something that will kill the mosquito, and then having found it, to apply it. It seems to us at present writing to be a bigger problem to exterminate the mosquito than it is to control malaria with quinin. We can kill the parasite in the blood of man more readily than in the system of the mosquito—or even than we can kill the mosquito itself. In other words, from an economic standpoint it may be a question whether it is not as

easy to take malaria and cure it with quinin, as it is to go on a still hunt after mosquitoes. This is a question in prophylaxis that has not much more than got itself stated. A solution of it is not yet in sight.

Blood Concentration.—Frequently the examination of the blood is one of the links in the chain of clinical evidence forged in the establishment of a diagnosis. A factor in blood examination which has received too little attention is the occurrence of blood inspissation, and this is worthy of more thoughtful consideration. In many instances a relative increase in the number of red corpuscles leads to false conclusions unless the important factor of concentration is carefully weighed, and therefore detracts from the value of blood examinations in diagnosis.

The causes of blood inspissation are numerous and constantly operative. A relative increase in the number of colored corpuscles occurs in such conditions as profuse sweating, diarrhea, persistent vomiting; the withdrawal of a large quantity of serous fluid from the body which is quickly replaced; by depriving the system of liquids, and by increased blood-pressure. Cabot, in referring to this subject, says: "In the presence, therefore, of any such reason for concentration, we should always modify our ordinary methods of inference from the blood-count."

It is a well-established fact that in cholera during the stage of collapse very high counts are observed, sometimes reaching seven millions per cubic millimeter. Not less striking an illustration is the relative increase of the erythrocytes which occurs after a drenching night-sweat in phthisis. A very complex and difficult problem is to determine anemia in such diseases where excessive erythrocytolysis and concentration are both making progress. Under such circumstances we must reflect upon the physiology of blood regeneration, namely: That the liquid elements are rapidly restored, the erythrocytes more slowly, and lastly the hemoglobin is gradually replaced. Factors which demand careful consideration in an acute infectious disease presenting profuse diarrhea are, that excessive blood destruction and concentration are both active. However, in such instances, while we should expect a relative increase in the percentage of red cells, the hemoglobin would not show the same increase and the corpuscular richness in hemoglobin or color index would be reduced.

In conclusion, therefore, when the condition of the blood is to have an important bearing upon a diagnosis, the results of such an examination should be compared carefully with such important clinical facts as the amount of liquids ingested and the rapid loss of fluids from the body.

The Improved Sanitary Condition of Havana.—Major and Surgeon W. C. Gorgas, chief sanitary officer for Havana, Cuba, in his monthly report for December,

1900, calls the attention of the Department Commander to the very excellent showing made by the vital statistics of the city for the last month of the century. We think some of these figures are worth quoting, for they reflect great credit upon the American officials who are responsible for the sanitary condition of Havana. The population of Havana is placed in round figures at 250,000. The number of deaths for December was 485. The smallest number for any December in the preceding 10 years was 517, in 1893. The death-rate for 1900 was 23.28. The next smallest for the past 10 years was 27.10 for 1899. The smallest death-rates for the past 10 years have been for these two years, 1899–1900; the years of the American occupation. There has been a marked decrease in the number of cases of yellow fever. In November there had been 214 cases with 54 deaths; in December 62 cases with 20 deaths. Dr. Gorgas calls attention to the fact that most of the yellow-fever cases occur in the recently arrived Spanish immigrants, more than two-thirds of the cases occurring in persons who have been in Cuba for less than one year. It is a noteworthy fact that Spanish emigration to Cuba still continues large; the number for December alone having been 4,206. This prevalence of the disease among these newcomers, who, of course, are not yet immune, is a striking instance of disease-propagation, and suggests strongly that some means ought to be devised to control it if possible. A prophylaxis, like Haffkine's for the plague, is evidently a desideratum. These figures from Dr. Gorgas' report show what can be and is being done to clean Havana and keep it clean. That city has been a more or less constant menace to the health of the American people, and it is gratifying to know that its temporary occupation by the United States Government is proving beneficial in a sanitary and hygienic sense. The lesson thus being taught ought not to be permitted to be forgotten or ignored in the years to come.

"Wiener medicinische Wochenschrift."—We extend to this valuable contemporary our heartiest congratulations on its fiftieth anniversary. We do not doubt that it will continue to maintain its customary prestige in the annals of medical journalism.

A Case of Rodent Ulcer Healed by the X-rays.—T. Stenbeck, of Stockholm (*Mittheilungen aus den Grenzgebieten der Medicin und Chirurgie*, Bd. VI, Heft 3), reports the case of a rodent ulcer of 9 years' duration, occurring on the bridge of the nose of a woman 72 years of age. The patient was subjected daily from 10 to 12 minutes to moderately strong x-rays, the lamp being removed 15 to 20 cm. After 4 sittings there was reaction; after 8 to 10 applications profuse suppuration, which, however, soon diminished. After 35 sittings, during which the ulcer was always cleaned, there followed desquamation of the epiderm. After a new, thin, smooth epiderm had formed, the intensity of the illumination was increased so that the patient was treated daily for 15 minutes with the tube removed but 10 cm. from the ulcer. Sufficient time has not yet elapsed to say whether a definite cure was established. [M.R.D.]

Reviews.

Enteroclysis, Hypodermoclysis, and Infusion. With a Chapter on the Carbonated Bath and Some New Applications; Also Therapeutic Addenda. By ROBERT COLEMAN KEMP, M.D. Introduction by Wm. H. Thomson, M.D., LL.D. Infusion, Shock, and Anesthesia, by Robert H. M. Dawbarn, M.D. Drawings by Thos. Nast, Jr. Photographs by Dr. A. W. Gardner. 8vo, pp. xiv, 349. New York: James T. Dougherty, 1900

It is a mistake to believe that the physician's armamentarium begins and ends with the *materia medica*. In fact, his most potent weapons, both of offence and defence, are at times drawn from other sources. The great value of water, administered in various ways, as a therapeutic agent has long been appreciated, and the little volume before us deals with its application through the intermediation of the bowel, the lymphatics and the bloodvessels. The subject has become one of great importance and a diffusion of knowledge bearing upon it must bear good fruit. Dr. Kemp has for a number of years devoted himself, experimentally and clinically, to the study of the matters in hand and is, therefore, qualified to discuss them with intelligence and judgment. The book is divided into five parts, one on enteroclysis, the second on hypodermoclysis, the third on infusion, the fourth on the carbonic acid bath, and the fifth on therapeutic addenda. In view of the inherent importance of the subject and the timeliness of publication the volume will no doubt be cordially received.

A Compend of Diseases of the Skin. By JAY F. SCHAMBERG, A.B., M.D. Professor of Diseases of the Skin, Philadelphia Polyclinic and College for Graduates in Medicine; Fellow of the College of Physicians of Philadelphia. Second edition, revised and enlarged. With 105 illustrations. 8vo, pp. xv, 291. Philadelphia: P. Blakiston's Son & Co., 1900. Price 80 cents.

Discriminatingly used, this little book is capable of aiding the student to a readier understanding of the subject with which it deals. It affords, so to speak, an outline, which must be filled in by clinical observation and wider reading. Duhring's classification is followed and special attention has been given to the differential diagnosis and treatment of the more important affections.

International Clinics. Edited by HENRY W. CATTELL, A.M., M.D. Vol. III. Tenth series, 1900. Philadelphia: J. B. Lippincott Company, 1900.

This volume contains a symposium of 7 papers on genito urinary diseases. Four papers on therapeutic subjects, 3 in medicine, 3 in neurology, 5 in surgery, 4 in obstetrics and gynecology and 1 each on diseases of the eye, laboratory methods and the scientific modification of milk; illustrated by 18 figures and 27 plates. The articles will appeal especially to the general practitioner, and that by Dr. Westcott on milk-modification is particularly commendable as it is an effort to elucidate and to simplify a subject that has been involved in a good deal of complexity and one that is at the same time of the utmost importance from a practical point of view.

A List of Publications of Dr. Irving C. Rosse, Washington, D. C.

This pamphlet contains a complete catalogue of Dr. Rosse's publications covering the full period of his professional life. Dr. Rosse is well known as a contributor to medical literature especially in the domain of neurology and psychiatry, and for those who desire to refer to his writings this list will be a great convenience.

Correspondence.

SUPRARENAL CAPSULE IN ORGANIC HEART DISEASE.

By SAMUEL FLOERSHEIM, M.D.,

of New York City.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I INTEND to publish a second paper on the use of the suprarenal capsule in organic heart disease. Will you kindly ask the readers of your JOURNAL to send me the reports of their cases as follows:

1. The condition of the heart and pulse, and also the pulse-rate.
2. The effect on the heart and pulse, and also the pulse-rate, within 10 minutes after the suprarenal powder, 3 grains, is chewed and swallowed without water, by the patient.

218 E. 46th St.

DR. JACOBI'S ADDRESS.

By HAROLD N. MOYER, M.D.,

of Chicago, Ill.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN the presidential address before the Mississippi Valley Medical Association I referred to the address of Dr. Jacobi before the International Medical Congress as misrepresenting the medical profession of America. At the time my address was prepared I had not seen the address of Dr. Jacobi, but my information was derived from more or less fragmentary reports that had reached this country, and certain editorial references to the address describing it as "apologetic."

A reading of the full text leaves a very different impression on my mind. Instead of apologizing the essayist pays a splendid tribute to the American medical profession, alike free from overstated claims, or hypocritical self-depreciation.

I certainly very much regret the reference to Dr. Jacobi's address, but feel that I must in part be exonerated as I accepted statements which seemed authoritative.

The whole matter reveals a phase of medical journalism that I little suspected.

"ANOTHER FACTOR IN THE TRANSMISSION OF
DISEASE GERMS."

By E. D. FREAR, M.D.,

of Sloan, Ia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

DR. LEIDY's communication in your JOURNAL of January 12, calls to mind another "Factor in the transmission of diseased germs" to which, so far as I know, the attention of the medical profession has not been called.

I refer to the pestiferous pack peddlers. This class of mendicants is usually composed of an undesirable class of aliens whose ideas of hygiene, or even of common cleanliness, are very limited. Whenever they can gain admission to a house, their packs, which are generally made up of fabrics which are good conveyors of diseased germs, are opened and spread over sofas, beds, and other convenient articles, and are promiscuously handled by the members of

the household. The air of the room may be impregnated with the desquamations of variola or scarlatina, the exudations of diphtheria, or the expectoration of tuberculosis. The goods are carefully repacked and carried to the next home, or several homes, where the germs are distributed. Without going into details, I have seen two developments of scarlatina and, one of diphtheria, in each case a clear history of the contagium being carried in this manner. I recognize the fact that our cities and more populous communities are spared this nuisance, but it is in the country, where the population is sparse, and where, in many cases the disease is in so light a form that a physician is not called, that this danger exists.

SURGICAL INTERVENTION IN PERFORATION IN TYPHOID FEVER.

By WILLIAM OSLER, M.D.,

of Baltimore, Md.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In your editorial note on surgical intervention in perforation in typhoid fever, you lay stress upon the effect of the anesthetic. In a majority of our cases the operation has been performed under cocaine, with which the patients apparently suffer very little distress. In illustration of the capacity of a patient to stand repeated surgical interference, I may refer to a case already reported by Dr. Cushing in the *Johns Hopkins Bulletin*. Three operations were performed within two weeks, the first on August 13, under chloroform anesthesia, when a perforation was sutured; 13 days later the patient suddenly became worse, had vomiting, was collapsed, restless, and the abdomen was distended, and he had hiccough. He was thought to have another perforation, and was operated upon under chloroform, but nothing was found to account for the symptoms. Two days later he had much more serious symptoms, and a third operation was performed, also under chloroform. A perforation 1 cm. in diameter was found and sutured, and the bowels were irrigated with salt-solution and replaced. He made a satisfactory recovery.

THE INDIVIDUAL COMMUNION CUP.

By HOWARD S. ANDERS, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

As one who is—as the phrase goes—"largely responsible" for the agitation in favor of the adoption of individual communion cups as sanitary and not less sacred substitutes for the single and several commonly-used chalices and cups, I may refer, with propriety, perhaps, to Dr. Sheaff's letter, in your last issue of the *JOURNAL*, concerning this matter in relation to the prevention of tuberculosis. I have written and spoken so often on this subject that I hesitate before putting forth again, lest the reform may be harmed more than helped by my apparent position as an unbalanced hobbyist or sacrilegious sanitarian.

And yet, it seems that the underlying facts and principles of the individual cup idea, as applied to schools as well as to churches, are quite obvious to every right-thinking and progressive physician. So that, while letters like Dr. Sheaff's are encouraging and gratifying from the interest shown, after all, what are physicians doing in a personal, hand-to-hand, practical way to further this sanitary reform in the churches?

The Philadelphia County Medical Society passed a resolution, after my first paper on the subject, in September, 1894, favoring the adoption of individual communion cups; ministerial conferences and assemblies have done likewise. Nevertheless, the passing of resolutions accomplishes very little in the way of actually bringing things to pass, unless the physicians themselves work quietly, rationally, and with tact and persistence among their patients, friends, and own church fellow-members.

Surely, not rarely may the occasion be opportune for the family doctor to ask, Does your church use individual communion cups? and if not, according to the reply, an influential word may be uttered. Especially does this bring fruitage among women, who are often instrumental in inducing a strong and successful sentiment against the single chalice or cup. Since the clergymen are very few who will head the movement in their own churches, for reasons of propriety, but many who will readily sanction it, it is evident that the initiative in agitation and action must come from the people and church officers; and these will not move unless their medical advisers teach, awaken, and encourage them to do so.

"True it is," writes Dr. Sheaff, "that some congregations have adopted the individual-cup method; but are they many, compared to those who have not?" No, indeed, they are not many. My latest statistics—approximate—show that there are not more than about 800 churches (representing about 500,000 communicants) in the United States using it. This is more than twice as many as in 1893, but a small number compared to the thousands not doing so. However, the movement is steadily, though slowly, growing all the time. *Medical men only can hasten it*, primarily, as hinted before.

It should be urged, further, that the method is not only satisfactory in hygienic principle, but equally so in practice, as all churches using it unanimously testify; not only clean and sanitary, but permitting also as much of solemnity, dignity, impressiveness, and devotional concentration as by the use of a single cup or of half a dozen cups by many mouths of uncertain cleanliness and health.

We should think not only of tuberculosis, but of prevalent influenza, and follicular tonsillitis—to mention no other transmissible diseases in this connection; they may all "go to church" with their hosts, in some communicable form. The recent discussion in the *London Lancet* and some of the English church papers concerning the revival of intinction as a mode of administering the sacrament, as well as the individual communion cup, shows the trend of feeling in the direction of more general ecclesiastical sanitation than now obtains in celebrating the memorial of the Lord's Supper.

THE CURE OF URETHRORECTAL FISTULA.

By RICHARD N. GIBBONS, M.D.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

DR. THOMAS ADDIS EMMET, nearly a third of a century ago, operated through the rectum for the cure of urethrorectal fistula. In the third edition of his masterful work on gynecology, the following and additional notes will be found relative to the case, and for the benefit of your readers, including Prof. Horwitz and Prof. Keen, I offer for publication, quoting from the above as follows:

"CASE 108.—On May 28, 1870, I closed a rectourethral fistula in a gentleman from Kentucky, at the request of the late

Dr. J. C. Nott. The case was reported,¹ but without giving the operation in detail, and I now give it in full, as it seems to illustrate well the manner of closing from the rectum similar openings in the female organs.

"On the first of December, 1868, a large stone of irregular shape, weighing 5 ounces, was removed by the lateral operation, which left a fistulous opening in the rectum, through which the urine passed. A portion of the urine continued to discharge by the rectum up to the time of his arrival in New York, and no attempt had been made to close the opening. Not only did a portion of the urine pass through the rectum, but fecal matter and gas frequently escaped with the urine through the urethra. The feces sometimes formed an annoying temporary obstruction to the passage of the urine through the penis. The bladder was irritable, requiring the urine to be passed off more frequently than natural. The rectum was also irritable, but less so than is usual in urinary fistula opening into it. I had no opportunity of examining the case until I was called upon to operate. When the parts were brought into view by placing my self-retaining speculum in the rectum, two oval openings were seen about an inch apart, one leading into the bladder and the other to the urethra.

FIG. 149.—Rectourethral fistula in a man (from the rectum)."

"Between these openings a narrow strip of urethral mucous membrane could be traced, which represented all that remained of the membranous portion of the urethra. The appearance was as if a section had been removed by a sharp knife, so as to leave a small, narrow portion in the center. The facility with which I succeeded in closing this opening, by supplying the loss from rectal tissue, led me subsequently to employ the same method for closing certain cases of recto-vaginal fistula. The rectum in this neighborhood forms a double concave surface, due to its direction, its long diameter, and its cylindrical shape.

"On a correct appreciation of this fact rested the success of this operation. I soon ascertained, by experimenting with the tenaculum, that, if I should denude a portion of rectal surface of a uniform width, in two parallel lines, from one opening to the other, I should not be successful in forming a urethral canal. This, doubtless, was the most obvious mode of procedure, and yet it was evident that, if these freshened surfaces were turned over and brought in contact, there would result a narrowing in the center in the shape of an hour-glass contraction. In order, therefore, to reconstruct the membranous portion of the urethra in this case, it was

necessary to remove the mucous membrane from the rectal surface in the form of an elliptical space, as shown in diagram Fig. 149. Four of the sutures are there represented to have been introduced, for the purpose of showing that when these were tied the denuded spaces A B, Fig. 149, would form a canal of uniform width, and the line of union would lie in the direction C D in the long axis."

It will be noted by observation of the accompanying sketch, reproduced for me by my son, Dr. Horace J. Gibbons, from the original cut in Dr. Emmet's work, marked "Fig. 149," and by studying the above quotation from the same work, that his attempt to repair the loss due to destruction was not made through any haphazard method, but, like all the work of this distinguished surgeon, it was planned from an anatomical viewpoint, every consideration being given to the physiological necessities dependent upon the pathological conditions; hence this operation was not done merely to close the fistulous opening, but in addition thereto to restore the membranous portion of the urethra, this being done with tissues that are ideal when histologically considered.

Emmet was the first man in all the world to teach the possibilities of dire disaster being brought about by granulation repair, the resultant scar-tissue often, by its cicatricial contraction, impinging upon the filaments of the sympathetic system of nerves, producing thereby reflexly a most expressive word-torment in more or less distant portions of the nervous system, even to the extent of upsetting the mind.

Then, too, if this operation was not properly planned, as was done by Dr. Emmet, the "hour glass" contraction of which he speaks would have produced more or less obstruction of the urethral canal stricture. This would have happened in Dr. Horwitz's case had the suggestion, made by Professor Keen, the use of the thermocautery, succeeded in healing the fistula, which would have been by granulation.

It must be borne in mind, too, that Emmet uses almost exclusively the silver-wire suture, which is preferable to any other in plastic surgery, where we are most anxious to have union primarily, as in the work upon the genital and urinary organs.

Primary union, too, is more likely to be attained where the delicate tissues of fistulae in general are handled by the tenaculum, as is so deftly done by Dr. Emmet, instead of pinching them by means of hemostatic or other forms of tissue-holding instruments.

The wire suture can be quickly, easily, and painlessly removed, merely using Emmet's size of Sims' speculum through the anus, the patient being in Sims' position, or in the Emmet-Bosman-Agnew Otis method, the knee-chest method of posture for examining or otherwise dealing with the rectal pouch.

If patients are properly prepared as has long since been taught and practised by Dr. Emmet, and if they are kept on the right sort of food, there is no necessity for giving opium, neither is there any necessity for the use of any form of clasp-trap contrivances.

Cutaneous Affections Caused by the Oxyuris Vermicularis.—Barbagallo (*Gazz. degli ospedali e delle clin.*, 1900, No. 111) calls attention to a case of inflammation of the skin of the thigh and around the anus, caused by the oxyuris vermicularis. The erosion of the skin, caused by scratching, offers a suitable soil for the parasites and their ova. The diagnosis is established by microscopic examination and the efficiency of anthelmintic treatment. According to the author, his case is the fourth reported. [M.R.D.]

¹"Case of Rectourethral Fistula," by J. C. Nott, M.D., *N. Y. Med. Jour.*, September, 1870.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Scarlet fever is prevailing in New Jersey, the school-houses of Vineland, Cape May county and Swainton have been closed and the church services suspended.

Bacteriologist Appointed.—William R. Copeland, of Pittsburg, was appointed to succeed bacteriologist Toplis, of the city's filtration force, whose resignation is announced.

Influenza in Allentown.—Several schools in Allentown have been closed on account of influenza, and the business of the city is hampered in general on account of the disease.

Appointments.—Dr. Oliver J. Bennett, Allegheny, Pennsylvania, has been appointed physician to the Western Penitentiary of Pennsylvania. Dr. Charles B. Smith has been appointed surgeon of the Lackawanna railroad at Washington.

Deadlock Ended at Norristown.—The deadlock of the trustees of the State Hospital for the Insane over the election of a resident physician for the female department was ended on January 18 when Dr. Alice Bennett withdrew her name as a candidate and Dr. Mary Moore Wolfe was elected.

The Practitioners' Society of Orange, N. J.—At the first annual meeting of this society, held on January 5, officers were elected as follows: President, Dr. Edgar Calvin Seibert; vice-president, Dr. J. Minor Maghee; secretary and treasurer, Dr. Stephen G. Lee; executive committee, Drs. M. Herbert Simmons, Walter Dodge, and Frank B. Lane. Dr. Edward J. Ill, of Newark, and Dr. Thomas W. Harvey, of Orange, were elected honorary members.

Philadelphia Medical Club.—At the annual meeting held January 11, the following officers were elected for the ensuing year: President, Dr. E. L. Duer; vice-presidents, Dr. John B. Deaver, Dr. Philip Marvel, of Atlantic City; secretary, Dr. Guy Hinsdale; treasurer, Dr. F. S. Pearce; member of the board of governors, Dr. James M. Anders; executive committee, Dr. T. C. Fulton, Dr. James Van Buskirk, Dr. L. Webster Fox, Dr. Ernest Laplace, and Dr. G. G. Davis.

College of Physicians.—The report of the Library Committee of the College of Physicians of Philadelphia shows that on November 1, 1900, the library contained 61,359 volumes; and in addition the following: Duplicates, 4,140 volumes; unbound reports and transactions, 6,416; unbound pamphlets, 40,114. During the year 4,158 volumes were added; 10,442 books and journals were issued to readers in the library, and 2,411 books and journals were issued to Fellows of the College. There were registered 4,581 visitors during the year.

Philadelphia Neurological Society.—The stated meeting to be held on January 28, at 8.15, in the lower hall of the College of Physicians will be devoted to a Symposium on Brain Tumor.

The following papers are to be presented:

"Paresis, with Symptoms of Brain Tumor," by Dr. Wharton Sinkler.

"A Case of Brain-Tumor, with Hemiplegia, Homonymous Hemianopsia and Wernicke's Symptom," by Dr. F. X. Dercum.

"A Case of Extensive Endothelioma of the Brain," by Dr. John K. Mitchell.

"A Case of Tumor on the Pons, Medulla Oblongata, and Upper Part of the Cervical Cord," by Dr. W. G. Spiller.

"The Localization of Brain-Tumors, Especially with Reference to the Parietal and Prefrontal Regions, Based on Five Cases in which the Sites of the Tumors were Located for the Purpose of Operation," by Dr. Charles K. Mills.

"A Case of Unilateral Oculomotor Palsy Probably Due to a Gumma," by Dr. D. Riesman.

"A Case of Subcortical Brain-Tumor," by Drs. Charles K. Mills and Howard D. Geisler.

The discussion will be opened by Dr. G. E. deSchweinitz

and Dr. William J. Taylor. Members of the medical profession are cordially invited to attend the meeting.

Vital Statistics of Philadelphia for the week ended January 19, 1901:

Total mortality	477	CASES.	DEATHS.
Inflammation of appendix 4, bladder 1, brain 13, bronchi 12, kidneys 22, lungs 77, peritoneum 7, pleura 2, stomach and bowels 15, spine 2, of larynx 2, of liver 1, heart 3	161		
Inanition 12, marasmus 3, debility 16	30		
Tuberculosis of lungs	51		
Apoplexy 19, paralysis 5	24		
Heart—fatty degeneration of 4, dropsy of 31	35		
Uremia 14, diabetes 3, Bright's disease 4	21		
Casualties	11		
Carcinoma of breast 1, stomach 7, uterus 2, jaw 1, rectum 1, liver 4	16		
Convulsions	7		
Diphtheria	17	118	
Brain—softening of 1, congestion of 2	3		
Typhoid fever	12	51	
Old age	14		
Burns and scalds	1		
Dysentery	2		
Suicide	1		
Cirrhosis of liver	4		
Alcoholism	3		
Cyanosis	1		
Scarlet fever	2	70	
Hernia	1		
Asthma 1, congestion of the lungs 2, croup 1, membranous croup 4, diarrhea 2, dropsy of the liver 2, dropsy 2, drowned 1, epilepsy 1, erysipelas 3, gangrene 4, hemorrhage from kidneys 1, from stomach 1, uterus 1, influenza 8, consumption of bowels 1, intestinal obstruction 4, edema of lungs 2, poisoning 1, pyemia 1, rheumatism 2, sarcoma 1, surgical shock 1, septicemia 4, suffocation 2, teething 2, tetanus 1, ovarian tumor 1, whooping-cough 2	2		

College of Physicians; Section on Otology.—At the meeting of January 16, DR. GLEASON exhibited a case of **Unusual fracture of the nasal bones.** A copper rivet was forced, by the breaking of a belt, through both nasal bones lodging just under the skin of the opposite side. A discussion on **Mastoid operations** was opened by DR. STOUT and participated in by Drs. GLEASON and RANDALL.

Section on Gynecology.—At the stated meeting, held January 17, DR. CHARLES P. NOBLE reported a case of **Cancer of the cervix and pelvis following supravaginal hysterectomy.** Dr. Noble reported this case rather as a refutation of the claim that cancer of the stump is apt to follow supravaginal hysterectomy instead of a proof of that claim. He has performed that operation 175 times in cases of fibroids and a larger number of times for other conditions, this being the only case in which malignant disease followed. From the after-condition of the case there was reason to believe that unrecognized cancer existed at the time of the hysterectomy. DR. GEORGE EREY SHOEMAKER reported 2 cases: **A. Ovarian cyst followed by suppurating hematocele.** **B. Salpingitis with obscure localizing symptoms.** In the latter case the pain was principally in the gallbladder and epigastric regions. At first there was tenderness above Poupart's ligament and in the region of the appendix, but later the point of greatest tenderness varied from the epigastrium to McBurney's point. The diagnosis of salpingitis was made by vaginal examination under ether. Operation showed the tip of the appendix adherent to the right ovary, but the appendix appeared normal and was not removed.

DR. E. E. MONTGOMERY read a paper on **The treatment of prolapsus uteri.** Repair of the pelvic floor suffices, in some cases, with perhaps resection of the anterior vaginal wall. Greater degrees require ventral suspension in addition with, perhaps, shortening of the uterosacral ligaments. When there is a hernia in addition to the prolapse, Douglas's culdesac should be obliterated by uniting the peritoneum of either side. When the degree of prolapse is too great for these expedients hysterectomy is to be performed. The uterus should be brought out through the anterior vaginal fornix, the angiotribe being applied to each broad ligament and a ligature of chromicized catgut placed in the groove thus formed.

NEW YORK.

Mt. Sinai Hospital.—Dr. Hiram N. Vineberg has been appointed adjunct attending gynecologist to the hospital.

Bellevue Hospital.—A pavilion has been opened at Bellevue Hospital, New York City, for the reception of tuberculous patients.

Dr. Moore Reinstated.—The official reinstatement of Dr. J. W. Moore, of Bellevue Hospital took place on January 17, in the medical wards, by order of the Commissioner.

Dr. Eliphalet Nott, a well-known physician, died at his home in Rexford's Flats, Saratoga County, January 22, aged 67 years. He was a nephew of the Rev. Dr. Nott, for many years president of Union College.

By the will of James D. Sarven, of Tarrytown, the residuary portion of his estate, which amounts to \$226,563, is to be equally divided between St. Luke's and the Presbyterian Hospitals and the Bible and Tract Societies, of New York City, making the share of each \$59,140.91.

The Buffalo Academy of Medicine—Section of Obstetrics.—The regular meeting of this section was held Tuesday, January 22, 1901, at 8.30 P.M. The following papers were presented: "Symphysiotomy," by Dr. P. W. Van Peyma. "The Kidneys and Their Relation to Operations," by Dr. Stephen Y. Howell.

New York Orthopedic Dispensary and Hospital.—The trustees of the New York Orthopedic Dispensary and Hospital announce that the surgeon-in-chief, Dr. Russell A. Hibbs, will give a course of clinical lectures on Orthopedic Surgery at the institution, on Monday and Thursday afternoons, at 5 o'clock, from January 28 to February 28 (both inclusive). The course will be free to the medical profession and students.

Photographs of Surgery.—Experiments lately made by E. H. Fairchild in the operating rooms of the Albany Hospital have proved that it is possible to procure a series of photographs of a surgical operation and thus to provide lantern slides as a basis for surgical instruction. Operations by Drs. Albert Vanderver and Willis G. MacDonald have been successfully photographed in series, each stage in the operation being represented by a photograph taken instantaneously, and without in any way interfering with the operation. Students of surgery find it difficult to secure satisfactory instruction, because during the operations the surgeons are too much absorbed to lecture, and afterward the opportunity is gone. By means of a special camera a series of photographs can be taken, showing all that any student can see, and with these as a basis, the surgeon can give an illustrated lecture describing the operation in detail.

New York Academy of Medicine—Section on Orthopedic Surgery, meeting of December 21, 1900.

Reposition of the Congenitally Dislocated Hip.—Dr. ELY, in a recent visit to Vienna, had spent some time in observing the practice of Lorenz, who was receiving cases of congenital dislocation of the hip from all parts of Europe. The cutting of tendons and instrumental traction were rarely seen. When the head of the bone had been replaced with suitable force and manipulation, the reduction was maintained by a most elaborately applied plaster-of-paris spica, which did not include the trunk, and extended only to the knee. The patient was then sent home to stay several months. The results were good, and sometimes so brilliant as to justify the enthusiasm of the operator, who believed that when a knowledge of the operation was widely spread reduction would be made at such an early age as to almost preclude the possibility of a failure. The remarkable statistics of successes which had been published had their origin partly in enthusiasm, and partly in the undoubted excellence of a method applied with requisite technic.

Dr. H. L. TAYLOR reported that the experience of Calot in his hospitals at Berck, on the channel coast of France, had showed that the bloodless reduction of congenital dislocation of the hip was applicable in children up to 8 years of age, or later in exceptional cases. Active treatment covered from 6 to 22 weeks and included 2 or 3 weeks' traction with

a weight of from 10 to 20 pounds, and at the operation the application of a force of 300 pounds for 10 minutes to bring the head of the bone down to or below the acetabulum. When the retaining apparatus was removed, massage and training in walking completed the treatment. Patients had recovered without the trace of a limp. He had practically given up the open method. The correct attitude obtained by cutting would be at the expense of limitation of motion or ankylosis, which might be properly sought by this method in certain cases in which replacement was impossible.

Dr. R. H. SAYRE had seen Lorenz operate last year in Paris at the Redard clinic. The patient, a child of about 8 years of age, was moderately disabled by a single dislocation of the hip. The thigh was made to form an angle of perhaps 20 degrees posterior to the plane of the body. A great deal of force was employed for this and in turning the limb in various directions. The head of the femur could be heard as it popped around on the ilium in what must have been a mass of lacerated tissues. The spica, which was nearly 2 inches thick where the strain came, included two loose strings for subsequent use in scratching the skin and keeping it clean. The head did not assume a permanent residence in the acetabulum. It was said that it would do so after the child had walked about for a year or two in the spica, a question which would have to be answered in due time.

Dr. C. H. JAEGER had recently spent 6 weeks at Vienna and reported that the treatment of congenital dislocation at the Lorenz clinic was exclusively by the bloodless method. Double cases were treated singly. The results were very favorable. The spica was applied with great care. Only a thin layer of cotton padding was used. The plaster bandage was applied very snugly, the thigh only being enclosed and a narrow strip going about the pelvis. This left the knee and ankle free and also the whole spinal column. The limb being thus fixed in extension and abduction, the patient soon learned to walk without crutches and with (in single cases) a high sole on the sick foot. It was most interesting to see a child with double dislocation, with both legs strongly abducted, spread-eagle fashion, walking beautifully, hopping with one leg, then the other, without a stick or help of any kind. Lorenz was accustomed to lay great weight on having the parents of the patients extend the knee many times daily, to prevent contracture. In opposition to these views Hoffa strongly advocated the open method.

Dr. R. W. TOWNSEND said that Hoffa had stated in very positive terms that none other than the bloody operation could be of any use. An American authority also had reported that in a large number of open operations only 2 or 3 had exposed an acetabulum in which it was possible to place the head. The views and practice of Lorenz, however, were those of one whose experience with the open operation had been greater than that of all other operators combined. In one of the dissections reported by Dr. E. H. Bradford the capsule had been found pushed in front of the head of the bone in such a manner that perfect reduction could not be made. This had led to the suggestion that in some cases the open operation might be modified by slitting the capsule instead of gouging or boring the bone which might lead to ankylosis or limited motion.

Dr. JAEGER thought that Hoffa was dissatisfied with the bloodless procedure partly because of the position in which he fixed the limb after reduction of the deformity. He applied the spica with the limb in extension and strong inward rotation, which could not afford a very firm hold for the femoral head in the acetabulum. In this position it was probable that the relaxation would occur during the application of the bandage or on the first attempt at walking.

Dr. T. H. MYERS said that those American surgeons who, after trying both methods, favored the opening of the joint in every case, were at variance with Lorenz. In his own experience, which had been considerable, he had not yet opened a joint, believing that the bloodless method should be tried first. It secured some perfect results, and in the results which were not perfect the head was placed anterior to or above the acetabulum, which was better than to leave it on the dorsum.

Dr. G. R. ELLIOTT had passed several weeks with Lorenz in 1896 and had seen him operate many times by the non-cutting method, having already begun to discredit the cutting operation, which he had done so much to perfect. There could be no possible doubt of the good results obtained. He

had seen many instances and had repeated them in his own practice. Success lay in the thoroughness of the procedure and in the perfection of the technic. 1. The head of the bone should be brought down to the level of the acetabulum. 2. It should be lifted over the posterior edge of the acetabulum. 3. Abduction should be extreme, even posterior to the mid plane of the body. 4. The plaster bandage should be pressed posteriorly against the joint to keep the reduced head from slipping backward. Great force was often required, but neglect of any point would leave the head of the femur resting on the posterior acetabular edge to be dislocated as soon as the bandage was removed. Lack of success would be due to want of technic leading to imperfect reduction. Thorough padding was necessary beneath the bandage. Blood had appeared in the urine of a patient operated on by him last week. The child had been laid face downward to facilitate fortifying the splint posteriorly, and the soft plaster bandage had pressed against the abdomen and hardened. Cutting bandage relieved pressure, and blood disappeared.

Sea-Air for Tubercular and Rickety Patients.—DR. TAYLOR in his review of the treatment at Berck said that Calot was an enthusiastic advocate of sea-air for patients affected with external or peripheral tubercular lesions, those of the skin, glands, bones and joints. He rejected phosphorus in the treatment of rickets, prescribing intestinal antiseptics and a diet mainly of milk and eggs. Many of his patients were kept recumbent. He affirmed that rickety deformities would disappear during a sojourn at the seaside.

DR. SAYRE had listened to Calot as he described the advantages of seaside treatment. His interest in the subject was shared by others of his countrymen, whose native enthusiasm perhaps lent a too rose-colored light to their views.

DR. TAYLOR had been impressed with the picturesque quality of Calot's writings. His zeal often broke through the conventional boundaries of scientific composition. The reader was entertained and delighted, but not necessarily convinced.

Treatment of Pott's Disease.—DR. ELY said that Lorenz used a corset composed of perforated strips of celluloid, metal bands and canvas. It laced in front and was probably sufficiently comfortable, but could not be said to "splint the spine."

DR. TAYLOR said that although Calot declared that neither braces, plaster-jackets, nor corsets could prevent or arrest the deformity, all of his patients wore the plaster jacket after subjection to manual pressure directed against the kyphos. In certain cases ablation of spinous processes without invasion of the tubercular territory was recommended in order to facilitate correction and avoid sores from pressure of the jacket. The use of suspension, the amount of manual pressure and the degree of lordosis to be enforced were points to be settled for each case. Severe pressure and all traumatism were to be carefully avoided, in marked contrast with the violent proceedings which called attention to the name of Calot in 1896, when he was claiming uniformly brilliant results from the outlay of all his strength on the kyphos supplemented with cuneiform resections in obstinate cases.

DR. SAYRE said that Calot's recent methods as he had heard him describe them varied but little from those of Dr. L. A. Sayre when he introduced suspension and plaster-of-paris jackets. Calot had, however, secured a distinct advantage in extending the jacket up to the chin instead of stopping at the top of the sternum, thus promoting lordosis even of the lumbar spine and gaining a leverage over the entire spine, which was impossible when the upper part of the vertebral column was free.

Treatment of Joint-Diseases.—DR. ELY said that at the Lorenz clinic joint diseases generally were treated by retention in plaster of Paris. The spica for hip-disease usually had an iron stirrup running down from the bottom to take up the weight of the body.

DR. JAEGER said that Lorenz taught that traction *per se* did no good in hip-disease except as it caused fixation and that fixation alone was necessary, as the inflamed joint could well bear the weight of the body so long as there was no rubbing of the joint surfaces.

DR. TAYLOR said that Calot very justly believed that a stiff joint in a good position was better than a movable joint in a bad position. It was his practice to reduce the deformity by force and retain the improvement with a plaster spica.

Complete ankylosis in a bad position required subcutaneous osteotomy of the femoral neck.

Treatment of Abscesses.—DR. JAEGER had noticed fewer abscesses in patients affected with hip-disease at Vienna than in patients of the same kind in America, which was not easy to explain except by climatic differences, as the poor there were poorer, and their nourishment probably worse, than in this country.

DR. TAYLOR said that Calot forbade incision, curetting and excision in Pott's and hip-disease unless the joint or abscess was infected or a sequestrum was found. He took the ground that patients affected with these diseases practically always got well under closed treatment and always died under the open treatment. Abscesses were to be treated by roborant drugs, a full diet, correct hygiene and rest. A cold abscess might be aspirated through healthy tissue and medicated by injections. By repeated aspirations and the application of compresses and bandages openings which seemed inevitable might be averted and in from 4 to 8 weeks the abscess would disappear without a scar and with healing of the bone in most cases. It was interesting to note that we had (1) in Calot a surgeon of 10 years' active experience, formerly an advocate of scraping, incisions and excisions, with the reputation of having done 80 excisions of the hip, who was now aggressively opposed to the operative treatment of diseases of the joints, and (2) in Lorenz a surgeon of great experience in the cutting treatment of congenital dislocation of the hip who had given it up in favor of a bloodless method. The coincidence and the contrast between the recent past and the present were quite impressive.

Lateral Curvature from Division of the Spinal Accessory Nerve.—DR. R. A. HIBBS related a case as follows: A girl 14 years old had had glands removed from the left side of the neck 6 months before she was first seen a few days ago. There was spinal curvature toward the right with drooping of the left shoulder, paralysis and atrophy of the trapezius and marked disability of the left arm. The patient declined an operation for uniting the ends of the spinal accessory nerve, which had evidently been severed at the point where it pierced the sternocleidomastoid muscle.

DR. MYERS recalled the case of a similar patient, 15 years of age, whom he had been observing for 3 or 4 years. He saw her 18 months after the paralysis, and considerable permanent atrophy of the muscles of the shoulder, had set in. There was spinal curvature toward the opposite side which did not go on to be extreme and was easily controlled.

Fracture of Cervical Vertebrae.—DR. SAYRE related the case of a man who was carried home unconscious after a fall on the head and neck about 2 months ago. On regaining consciousness there was paralysis of the extremities, bladder and rectum, in which there was slow improvement after 2 days. As every attempt to walk increased his symptoms he was kept in bed several weeks. A diagnosis of fracture and dislocation of the fifth and sixth cervical vertebrae was made on his history, the fixation of the head, the absence of motion of the head and neck, difficulty in swallowing and the disability of the left upper extremity. The diagnosis was confirmed by skiagraphs, of which it had been necessary to take several from different points of view. One of the negatives was taken after fastening a bandage tightly over one shoulder and under the opposite arm-pit so as to make a gulch in which one edge of the plate had been forced so far as it would go. The skiagraphs and a brace were exhibited. The latter consisted of a leather and steel collar attached to posterior steel rods and a pelvis belt. The head and neck would be thus fixed until consolidation was assured, the brace being capable of easy modification from time to time as the patient improved. He recalled an almost exact counterpart in a case which occurred several years ago in which the application of a jacket and jury-mast had been followed by disappearance of the paralysis.

Pneumatic Perineal Straps.—DR. MYERS exhibited rubber tubes, 10 inches long and 1½ inches in diameter, designed to take the place of the ordinary perineal straps. Smaller sizes were also made. Each tube was provided with a removable cover of Canton flannel and a valve for inflation by a bicycle pump. The straps were not elastic. They were expensive, but very durable. The pressure made by them was equalized automatically, and that made them especially comfortable for older children and adults whose weight made perineal support difficult.

NEW ENGLAND.

Harvard University.—A chair of hygiene is to be established at Harvard, \$156,000 having been donated for this purpose.

Smallpox in Manchester.—The smallpox situation here is no longer confined to one district, but cases are scattered throughout the city. Eleven cases were found in the Notre Dame Orphanage, where there are 300 or 400 children.

CHICAGO AND WESTERN STATES.

Attorney-General Oren decided that townships must erect hospitals for contagious diseases.

Resigned.—Dr. Louis Bazet has resigned as a member of the Board of Health of San Francisco.

Pest-House at Fargo.—A pest-house has been built at Fargo for the reception of smallpox cases occurring in that city.

Sanitarium.—The Governor of Illinois, in his message, recommends the enactment of a law creating the establishment of a sanitarium for the treatment of tuberculosis.

Meeting of Medical Society.—The Witman County Medical Society, of Portland, Oregon, held its fourth quarterly meeting in Portland, on January 16. Papers were read by Dr. W. W. Watkins, of Moscow, and Dr. R. C. Coffey, of Portland.

State Board of Pharmacy.—A meeting of the State Board of Pharmacy was held in Jefferson City, Missouri, on January 14. The Board is composed of Dr. A. Brandenberger, Jefferson City; A. T. Fleishmann, Sedalia, and W. B. Kerns, Bunceton.

Dr. Benjamin Brown, of Chicago, Illinois, died at the Ebbitt House in Chicago, on January 18. Dr. Brown was a well-known physician of the Western metropolis. He had been ill for 2 years. A sudden heart attack, after a 2 weeks' racking illness, terminated his life. He was 66 years of age.

Dr. John Kost, a physician of Adrian, Michigan, who has several times made liberal donations to educational institutions, has given to the College of Medicine and Surgery of Chicago a museum of zoological specimens, valued at \$150,000. The articles filled 5 freight cars when prepared for shipment.

Dr. R. Beverly Cole, Coroner, of San Francisco, California, and one of the best known physicians on the Pacific coast, died on January 14, in his seventieth year. He was a native of Virginia, but received his medical education in Philadelphia. His specialty was gynecology, and for 30 years he was professor of that subject in the State University.

Dr. Charles Wesley Purdy died at Chicago of a complication of diseases. He was born in Kingston, Ontario, in 1846, and was graduated from the Queen's University with high honors. Dr. Purdy made a life study of diseases of the kidneys, and wrote several books on the subject. He received several degrees from the Royal College of Physicians and Surgeons of Canada.

Appointments.—Dr. I. Wright Short has been appointed surgeon of the Lake Shore and Michigan Southern Railroad at Elkhart, Ind.—Dr. Fred W. Powers, Reinbeck, Iowa, has been appointed a member of the State Board of Health to succeed Dr. Joseph H. Scruggs of Keokuk.—Dr. Victor C. Vaughan, of Ann Arbor, has been appointed a member of the State Board of Health of Michigan.

Osteopaths Not Physicians.—A bill to legalize and regulate the practice of osteopathy in Wisconsin was introduced in the State Senate on January 17. The bill does not permit its exponents to pose as physicians, and it is stated that the bill will afford no relief to persons charged with practising medicine without a license. The bill expressly declares that osteopathy cannot be construed to be the practice of medicine and surgery within the meaning of the statutes on that subject.

Rev. Charles E. Conard, M.D., died at Quincy, Ill., aged 81. He was born in Siberia, and educated for the church and medicine at Berlin; went to British India in 1848, and, as the missionary who could heal, was sought after by thousands of the natives. He established asylums for lepers and epileptics at Lohordagga; was in Calcutta during the Sepoy outbreak, and in 1853 came to America.

Dr. Thomas B. W. Leland, was appointed Coroner of the city and county of San Francisco, to succeed the late Dr. R. Beverly Cole. Dr. Leland holds the chair of assistant professor of physiology in the medical department of the State University; he holds the professorship of internal medicine in the post-graduate medical department of the State University and is also assistant surgeon of the State Naval Reserve.

Hospital for Insane Report.—The board of trustees of Milwaukee Hospital for Insane held their annual meeting on January 14, and elected the following officers for the ensuing year: President, B. B. Hopkins; vice-president, A. L. Cary; secretary, A. F. Wallschlaeger; ex-officio treasurer, the county treasurer, Schultz; executive committee, G. E. Gustav Kuechle, David Vance, J. W. P. Lombard; visiting committee, Christian Wahl, John F. Burnham, Miss Lillian Wall, Mrs. Anna L. Wall, Dr. Ernest Copeland.

Dr. William Hoskins Mullins, son of the late Professor Samuel G. Mullins, of Kentucky, died at Rock Island, Ill., on January 7. Dr. Mullins was educated at Center, Columbia and Yale Colleges, and was a man of rare gifts and attainments. During the civil war he was a surgeon in the Federal army and at different times was on the staffs of Generals Burnside and Thomas. For 10 years he was a great sufferer, having been left a physical wreck from an attack of yellow fever after having fought three epidemics of the disease in the South.

For a Western Medical Organization.—A Pacific medical association is about to be organized. The plan is to have San Francisco the center of a Western medical field, embracing Washington, Oregon, Idaho, Montana, Utah, Nevada, Arizona, California, Alaska, British Columbia, the Hawaiian Islands, the Philippine archipelago, and other islands of the Pacific, the western part of Mexico and of the Central American republics, and possibly the empire of Japan. A preliminary meeting of the most prominent physicians interested in this movement was held in this city on January 19.

Chicago Clinic.—With the January number the *Chicago Clinic* goes under the editorial management of Dr. Marcus P. Hatfield and Dr. George Thos. Palmer, who have purchased the property from the Chicago Clinical School. The *Clinic* was started 13 years ago as the *Omaha Clinic*, by Dr. J. Homer Coulter. The leading articles for January are: "The Limitations of Clinical and Microscopical Evidence," by Dr. W. K. Jacques; "Diet Kitchens," by Dr. Rosa Engelmann, and "The Jugulation of Lobar Pneumonia," by Dr. Louis A. Malone. As a leading feature for the year will be a department on "The Relation of the Law to the Practitioner of Medicine and Surgery," conducted by Hon. John Mayo Palmer, of the Chicago Bar and late counsel to the Corporation of Chicago.

Dr. Lewitt Takes His Seat on Health Board.—At a special meeting of the Board of Health of San Francisco, Cal., on January 12, Dr. William B. Lewitt, the newly appointed member of the body, took his seat after presenting his commission. Dr. Bazet introduced his successor, who was greeted by President Williamson with a few complimentary remarks. Williamson spoke of the storms that had gathered around the board and admonished the new members to stand firm when other storms should arise. Dr. Williamson was reelected president of the board to serve this year. Dr. Lewitt was appointed on the committees on publicity, food inspection, and finance. Dr. Buckley was made chairman of the hospital committee. The board decided to recommend to the Supervisors an amendment to the ordinance prohibiting the throwing of garbage on vacant lots by making it a misdemeanor for owners of the lots to allow them to be used for such a purpose. Violations are punish-

able by a fine of \$500 and imprisonment for six months. The Supervisors will also be requested to amend the ordinance prohibiting the use of cellars and underground apartments for sleeping purposes by making it more stringent in its operations.

Anti-expectoration Ordinance.—The following ordinance was passed in the city council of Chicago, January 14: "Whereas, spitting on sidewalks, in public places and in public conveyances is detrimental to health, by reason of the danger of spreading contagious disease, and is also a public nuisance which should be abated, therefore, Be it ordained by the City Council of the city of Chicago, that no person shall spit on any public sidewalk or on the floor of any public conveyance, or on the floors of any theater, hall, assembly room or public building; that any person violating the provisions of this ordinance shall on conviction be fined in a sum of not less than \$1 nor more than \$5; that this ordinance shall be in effect from and after its passage and approval by the mayor."

Chicago Pathological Society, regular meeting, January 14, 1901, Dr. L. Hektoen, president, in the chair.

DR. E. R. LECOUNT made a report on the **histologic changes** found in the tissues of animals inoculated with *diplococcus scarlatinae* (Class). The changes described differ only in degree from those described by Pearce and others in persons that die from scarlet fever, the most notable difference being the lack of lesions in the kidneys in the animals. Hyperplasia of lymphoid tissue, focal necrosis and plasma cells in situations that betoken their presence in the blood were found in the animals inoculated.

DR. W. H. WILDER read a paper on **tuberculosis of the iris** and showed specimens from a case observed by him.

DRS. D. R. BROWER and H. GIDEON WELLS reported a case of **paralysis of the cranial nerves** of the left side, from the fifth to the twelfth inclusive. This paralysis had come on in the course of a few months and then remained stationary for 12 years. At no time were there pressure symptoms. On account of the history, coupled with a slight improvement under iodids and the occurrence of 12 miscarriages, a syphilitic lesion involving the meninges and producing an infranuclear paralysis was diagnosed. Death resulted from nephritis. At autopsy a tumor was found in the dura, exactly as located clinically, involving the left petrous bone. Microscopically it was found to be an endothelial tumor, the periendothelioma of Borrmann, with some spiculae of bone and many multi- and uninuclear giant cells. Microscopically it resembled somewhat a psammoma.

DR. PAUL F. MORF presented **gross and microscopic specimens of three periosteal chondrosarcomas**. One of the tumors was from a boy of 13 and had developed on the tibia shortly after a contusion of that bone. The other 2 occurred in young adults, 1 in a female and the last in a male patient aged 19 years. These two latter tumors were found to have grown from the lower end of the femur. Microscopically the neoplasms all appeared as firm, hard, inelastic, grayish white masses. Scattered throughout their substance were numerous islets, which looked to the naked eye like hyalin cartilage. Disseminated foci of calcification of pinhead size gave the cut section a slightly rough surface. Microscopically, the tumors were found to be made up mainly of round and spindle-shaped sarcoma cells. The islets which appeared cartilaginous were made up of larger and smaller round encapsulated cells lying in a hyalin and in a fibrous intercellular substance. In the first of the 3 specimens the invasion of the Haversian canals of the tibia by sarcoma cells could be distinctly traced.

SOUTHERN STATES.

At the annual meeting of the St. Louis Academy of Science, Dr. Enno Sander was elected treasurer for the fortieth time.

Smallpox in Missouri.—Smallpox is rapidly spreading throughout the whole section of Northern Missouri and adjacent territory of other States.

Appropriation.—The Senate of Alabama unanimously passed the bill which appropriated \$25,000 to the Alabama-Bryce Insane Hospital at Tuscaloosa and for completing the department for negroes at Mount Vernon.

Howard Medical Association.—The annual meeting of the Medical Association of Howard County was held in Ellicott City, Md., January 5. Dr. William R. Stokes and Dr. Frank Martin, both of Baltimore, read papers.

The death of Dr. E. P. Becton, Superintendent of the State Blind Institute, occurred in Austin, Texas, January 14, at the age of 67 years. He was born in Tennessee, but had resided in Texas the greater part of his life, and was an old Indian fighter.

More Men Needed for Hospital Corps in Norfolk, Va.—The Surgeon-General of the Navy will shortly ask for the enlistment of additional men for the hospital corps. The vacancies now existing in this corps, of which there are no inconsiderable number, will be filled as rapidly as possible by enlistments at this and other naval stations.

Richmond (Va.) News.—Dr. Stockworther, of Prince William County, was dangerously hurt recently in a runaway accident.

The students of the Medical College of Virginia adopted the custom of wearing caps and gowns. This is the first medical school in Virginia to adopt this custom.

Cambridge Hospital.—The directors of the United Charities Hospital of Cambridge, Maryland, have elected the following local physicians as consultants: Drs. Thomas B. Steele and Thomas H. Williams, of Cambridge; Dr. Benjamin L. Smith, of Madison, Dorchester County; Dr. George P. Jones, of East New Market; Dr. Edgar A. P. Jones, of Lakesville; Dr. William T. Henry, of Hooper's Island; Drs. Edward R. Trippe and Charles B. Davidson, of Easton.

Ophthalmological and Otological Section—Richmond Academy of Medicine and Surgery.—There was a meeting of eye, ear and throat specialists of Richmond on December 31, 1900, at the offices of Dr. Joseph A. White, which resulted in the formation of the above-mentioned organization. It was decided to have meetings once a month except July, August and September. The early part of each session is to be devoted to business matters, reading and discussion of papers, etc.

Consolidation of the Marion-Sims College of Medicine and the Beaumont Hospital Medical College.—The governing faculty will include the following: Y. H. Bond, professor of gynecology and pelvic surgery; F. J. Lutz and Jacob Geiger, professors of surgery; W. A. McCandless, professor of surgery; C. Barck, professor of ophthalmology; W. G. Moore, professor of medicine; J. R. Lemen, professor of chest diseases; A. Alt, professor of ophthalmology; H. Summa, professor of medicine; L. H. Laidley, professor of gynecology and pelvic surgery, and clinical gynecology; B. M. Hypes, professor of obstetrics; J. Friedman, professor of clinical medicine and chemistry; H. W. Loeb, professor of nose and throat diseases; W. B. Corsett, professor of obstetrics and gynecology; R. C. Atkinson, professor of diseases of children; J. R. Dale, professor of surgery; C. G. Chaddock, professor of diseases of the nervous system; J. T. Larew, professor of surgical anatomy and clinical surgery; T. C. Witherspoon, professor of operative surgery on the cadaver and clinical surgery; M. A. Goldstein, professor of otology; G. C. Crandall, professor of medicine; C. M. Nicholson, professor of anatomy and clinical surgery; H. H. Born, professor of anatomy; R. J. Stoffel, professor of therapeutics; C. D. Lukens, professor of dentistry; S. I. Schwab, professor of nervous diseases; B. Lewis, professor of genitourinary diseases. In addition, the other instructors of the two institutions will be utilized to the fullest extent.

MISCELLANY.

Harvard University.—The total value of gifts made to Harvard University during the last year is announced as \$581,519.

Obituary.—DR. HENRY FOSTER, founder of the Clifton Springs Sanitarium, New York, died suddenly on January 14, aged 80.—DR. FRANK WERTS, of Longswamp Township, Kutztown, Pa., January 21.—DR. HIRAM CHRISTOPHER, aged 85, at St. Joseph, Mo.

A new building will soon be erected at Alker, Minn., to replace the sanitarium which was destroyed by fire about 6 weeks ago.

U. S. Commissioner of Immigration has decided that tuberculosis is a disease which may subject the patient to quarantine.

Delaware Hospital.—Dr. William W. Lesley, who died in Philadelphia recently, bequeathed \$11,000 to the Delaware Hospital in Wilmington for the support of two free beds.

Bequests.—By the will of the late Henry Villard, which has just been offered for probate, \$50,000 each is left to Harvard and Columbia universities, \$10,000 each to the German Hospital and Dispensary and the New York Infirmary for Women and Children, and \$5,000 to the Dobbs' Ferry Hospital Association.

Physicians of Havana recently gave a banquet to Dr. Carlos Finlay as a token of their congratulations for his theory regarding the transmissibility of yellow fever by the mosquito, which he has upheld for some time, notwithstanding the opposition, intolerance, and ridicule to which he has been subjected, until his observations had received recognition from the medical world.

Woodbridge Treatment.—The *Chicago Medical Recorder*, January, 1901, quotes the following: The Woodbridge method in the treatment of typhoid has not stood the test of experience. The opportunity of testing his method, accorded Dr. Woodbridge at the Fort Meyer Hospital, gave a mortality of about 10% as contrasted with a mortality of about 7% by usual methods.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended January 19, 1901:

Changes in Hospital Corps Designs.—The surgeon-general of the army has had under consideration the advisability of changing the chevrons and cap devices worn by enlisted men of the hospital corps of the army. The new designs proposed were last week submitted to Surgeon-General Sierenberg and have been approved on his recommendation by the secretary of war. The general order setting forth the changes will be issued shortly, a draft of it being now in preparation. The contemplated changes relate to the chevrons worn by privates, acting stewards and stewards of the hospital corps. The Geneva cross, which furnished a familiar insignia, will be abandoned in favor of a modified Maltese cross in the chevron. The body of this cross will be emerald green with a narrow white border. The cap device for the men of the corps will be a metal gold Maltese cross of smaller modification, which will replace the silver Geneva cross hitherto worn.

Changes in the Medical Corps of the U. S. Army, for the week ended January 19, 1901:

EDGER, First Lieutenant BENJAMIN J., Jr., assistant surgeon, now at the second reserve hospital, Manila, P. I., awaiting assignment, will report to the commanding general, department of Luzon, for duty.

The following named medical officers and acting assistant surgeons are authorized to proceed to Manila and report to the president of the Army medical board for examination for appointment as assistant surgeons, U. S. Army:

Department of Northern Luzon—Acting Assistant Surgeons J. RALPH SHOOK, HOWARD D. LEWIS, HORATIO P. BELT, ARTHUR D. PRENTICE, WILLIAM W. RENO and CALVIN D. SNYDER.

Department of Southern Luzon—Major WILFRED TURNBULL, surgeon, U. S. Vols., and Acting Assistant Surgeons PORTER V. BALLOU, R. BOYD MILLER, WILLIAM M. ROBERTS, CHARLES ST. JOHN, ARTHUR JORDAN, WILLIAM E. VOSE, GUSTAVUS I. HOGUE, and CHARLES L. BAKER.

Department of the Visayas—Acting Assistant Surgeons FREDERICK D. BRANCH, CONN R. OHLIGER, EDWIN C. SHATTUCK, and GORDON B. MELDRUM.

Department of Mindanao and Jolo—Acting Assistant Surgeons ROBERT B. GRUBB and A. BRUCE HENDERSON.

First Reserve Hospital—Acting Assistant Surgeons CHARLES W. FARR, and CHARLES J. FITZGERALD.

Second Reserve Hospital—Acting Assistant Surgeons FREDERICK A. DALE, CHARLES R. REYNOLDS, and PAUL T. DESSEZ.

Hospital No. 3—Acting Assistant Surgeons JOHN D. BROOKS and EDMUND BARRY.

Santa Mesa Hospital—Acting Assistant Surgeon FRANCIS M. McCULLUM.

Separate Brigade, Provost Guard—Acting Assistant Surgeons PAUL C. HUTTON, and JOHN M. FEENEY.

REYNOLDS, Major FREDERICK P., surgeon, granted leave of absence for 2 months, on surgeon's certificate, to take effect upon arrival in the United States, is relieved from duty as chief surgeon, separate brigade, provost guard, Manila, P. I.

MOSELEY, Major EDWARD B., surgeon, is relieved from duty as chief surgeon, department of Southern Luzon, and granted 3 months' leave of absence, on surgeon's certificate, to take effect upon arrival in the United States.

COMEGYS, Major EDWARD T., surgeon, is assigned to the command of the first reserve hospital, Manila, P. I., relieving Major William R. Hall, surgeon.

HALL, Major WILLIAM R., surgeon, will report to the commanding general, department of Southern Luzon, for duty as chief surgeon of that department.

ARTHUR, Major WILLIAM H., surgeon, will report to the commanding general, department of Northern Luzon, for assignment to duty.

SHREINER, First Lieutenant EDWARD R., assistant surgeon, will report to the commanding general, department of Northern Luzon, for assignment to duty.

MEACHAM, Major FRANKLIN A., surgeon, upon relief by Major William H. Arthur, surgeon, will report to the commanding general, separate brigade, provost guard, Manila, P. I., for duty as president of the board of health, Manila, P. I., relieving Major Guy L. Edie, surgeon.

EDIE, Major GUY L., surgeon, upon relief by Major Franklin A. Meacham, surgeon, will report to the commanding officer of the first available transport leaving Manila, P. I., carrying sick to the United States, for duty thereon while en route to San Francisco, Cal., reporting to the commanding general, department of California, for instructions to return to the division of the Philippines.

BANISTER, Major WILLIAM B., surgeon, will report to the commanding general, separate brigade, provost guard, Manila, P. I., for duty as surgeon of the Twentieth Infantry.

STEMEN, WILLIAM E., acting assistant surgeon, will proceed to his home, Kansas City, Kan., where he will report by letter to the Surgeon-General of the Army for annulment of contract.

CHAMBERLAIN, First Lieutenant WESTON P., assistant surgeon, is granted leave of absence for 1 month.

WADHAMS, First Lieutenant SANFORD H., assistant surgeon, on account of sickness, is granted leave of absence for 7 days, to

take effect from the expiration of the leave of absence granted him October 13, 1900.

SCHUMACHER, FREDERICK, hospital steward, now at Fort Huachuca, will be sent to Manila, P. I., for assignment to a station.

The following-named assistant surgeons will proceed from the places designated to San Francisco, Cal., for assignment to duty with troops en route to the Philippine Islands, where they will report for assignment to duty: GEORGE J. FANNING, from Sacaton, Ariz.; ALMON P. GOFF, from Caton, N. Y.; CHARLES E. JACKSON, from Canal Fulton, Ohio; JOSEPH W. LOVE, from Springfield, Mo.; THOMAS C. McSWAIN, from Bingham, S. C.; ROBERT C. ROGERS, from Bloomington, Ind.; JAMES W. SMITH, from Chicago, Ill.; GEORGE B. TUTTLE, from St. Louis, Mo.; JAMES BOURKE, from Chicago, Ill. HELLER, JOSEPH M., acting assistant surgeon, is granted leave of absence for 1 month, to take effect when a medical officer shall have reported at Fort Columbus to take his place.

NEWGARDEN, Captain GEORGE J., assistant surgeon, leave of absence for 1 month, granted November 15, is extended 1 month on surgeon's certificate.

HYSELL, Major JAMES H., surgeon, honorably discharged December 19, 1900.

THOMASON, Major HENRY D., surgeon, honorably discharged, December 31, 1900.

FAUNTLEROY, Captain POWELL C., assistant surgeon, U. S. Army, to be surgeon, with the rank of Major, November 30, 1900.

MATHEWS, First Lieutenant GEORGE W., assistant surgeon, U. S. Army, to be surgeon, with the rank of Major, November 30, 1900.

KNEEDLER, Captain WILLIAM L., assistant surgeon, U. S. Army, to be surgeon, with the rank of Major, December 1, 1900.

WILCOX, Captain CHARLES, assistant surgeon, U. S. Army, to be surgeon, with the rank of Major, January 3, 1901.

SHAW, Captain HENRY H., assistant surgeon, U. S. Army, to be surgeon of volunteers, with the rank of Major, December 19, 1900.

BRISTER, J. M., assistant surgeon, appointed assistant surgeon from December 14, 1900.

RODMAN, S. S., assistant surgeon, appointed assistant surgeon, from December 14, 1900.

Changes in the Medical Corps of the U. S. Navy, for the week ending January 19, 1901:

ANDERSON, F., surgeon, ordered home and to wait orders, when recruiting duty is completed.

LOWNDES, C. H. T., surgeon, detached from the Naval Academy, January 14, and ordered to the "Lancaster," via steamer from New York City, of January 19.

DIEHL, O., surgeon, detached from the "Lancaster" and ordered home, and to wait orders.

WARD, B. R., passed assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., January 17, and to the Boston Yard.

DENNIS, J. B., assistant surgeon, ordered to the Naval Academy, January 14.

DENNIS, J. B., assistant surgeon, to delay reporting for duty at Naval Academy until January 21.

PRYOR, J. C., assistant surgeon, ordered to duty at Naval Hospital, New York.

WILLIAMS, R. B., assistant surgeon, detached from the Navy Yard, New York, and to the Navy Yard, Pensacola.

LIPPITT, T. M., assistant surgeon, detached from the Naval Hospital, Yokohama, Japan, and to Naval Hospital, Mare Island, Cal., via "Solace."

WRIGHT, B. L., assistant surgeon, detached from the Naval Hospital, Yokohama, Japan, and to Naval Hospital, Mare Island, Cal., via "Solace."

BLAKE, Second Lieutenant D. W., detached from the Naval Hospital, Yokohama, Japan, and ordered to Naval Hospital, Mare Island, Cal., via "Solace."

TOMB, Naval Cadet W. V., detached from the Naval Hospital, Cavite, P. I., and ordered to the "General Alva."

REANEY, Chaplain W. H. I., detached from the Naval Hospital, Cavite, P. I., and ordered home via the "Solace."

Changes in the U. S. Marine-Hospital Service, for the week ended January 17, 1901:

SAWTELLE, H. W., surgeon, leave of absence for 30 days granted by Bureau letter of December 13, 1900, revoked. January 15.

MEAD, F. W., surgeon, granted leave of absence for 60 days from January 21. January 11.

GLENNAN, A. H., surgeon, detailed to represent the service at meeting of Third Pan-American Congress to be held at Havana, Cuba, February 4-8. January 16.

PETTUS, W. J., surgeon, granted leave of absence for 2 months from February 5. January 11.

NYDEGGER, J. A., passed assistant surgeon, granted leave of absence for 30 days. January 15.

THOMAS, A. R., passed assistant surgeon, to proceed to Shields, England, for special temporary duty. January 15. Relieved from duty at Glasgow, Scotland, and assigned to duty in the office of the U. S. Consul-General at London, England, December 28.

JAYINDER, C. H., assistant surgeon, to proceed to Vineyard Haven, Mass., and assume temporary charge of the service during absence of Surgeon F. W. Mead. January 16.

McMULLEN, JOHN, assistant surgeon, granted leave of absence for 21 days from January 21. January 16.

CRAIG, R. C., acting assistant surgeon, granted leave of absence for 7 days. January 17.

foreign News and Notes.

GREAT BRITAIN.

Dr. S. Gemmell was elected professor of the medical clinics of Glasgow, succeeding Dr. McCall Anderson.

Mr. Alexander Peckover, the Lord-Lieutenant of Cambridgeshire, has made a further donation of £1,000 to Adden Brooke's Hospital.

Lieutenant-Colonel J. Crofts, M.D., I.M.S., has been appointed surgeon to his Highness the Maharajah of Jodpore, and has proceeded to India to take up his duties.

British Congress on Tuberculosis.—As president, His Royal Highness, the Prince of Wales, will open in person a British Congress on Tuberculosis in the Queen's Hall, London, on Monday, July 22, 1901; the Congress will be held until July 26. The Congress will consist of delegates from British Colonies and Dependencies, while Europe, Asia and America have been invited to send representative men of science to be the distinguished guests of the Congress. The object of the Congress is to exchange the information and experience gained throughout the world as to methods available for stamping out this disease. Papers will be read, and clinical and pathological demonstrations will be given; while the museum, which is to be a special feature of the Congress, will contain pathological and bacteriological collections, charts, models, and other exhibits. Authorities in this and other countries will be invited to supply documents bearing upon the historical, geographical, and statistical aspects of the subject; while as a result of the papers and discussions, practical resolutions will be formulated which will serve to indicate the public and private measures best adapted for the suppression of tuberculosis. The work will be divided into four sections, as follows: (1) State and Municipal; (2) Medical, including Climatology and Sanatoria; (3) Pathological, including Bacteriology; (4) Veterinary (Tuberculosis in Animals), and the Exhibitions of Specimens.

RULES AND REGULATIONS.

The Congress shall consist of honorary members, delegates, and members.

1. Honorary members shall be persons nominated by any foreign government or university, or by the executive committee, and shall not pay any subscription whatsoever. Delegated and ordinary members shall be other persons, British, Colonial, or foreign, who may wish to attend, including representatives from governments or institutions within the British Empire.

2. Delegated and ordinary members will receive their cards on forwarding the sum of £1 to the secretary-general of the Congress, 20, Hanover Square, W.

3. The holder of a ticket of membership is entitled to admission to all the meetings of the Congress, and to receive the "Transactions" and other publications. Tickets to social gatherings and excursions will be allotted in order of application, or by ballot if necessary.

4. As the expenses of the Congress will be very considerable, donations to the reception fund are earnestly invited. Donations of more than one guinea will be considered as including member's subscription, and will entitle the donor to all privileges of membership. Donations from corporate bodies may include the subscriptions of representatives.

5. The official language of the Congress shall be English, French, and German, and authors of papers are requested to supply beforehand abstracts for translation.

6. Each sectional committee shall draw up its own working program as to papers to be read, discussions on the subjects proposed, and miscellaneous communications. The various sections will meet on Tuesday, Wednesday, Thursday, and Friday, from 9.30 to 1.30.

7. The speeches delivered at the general assemblies, and the papers read before the sections, will be published in the record of the proceedings of the Congress; but as regards miscellaneous communications and discussions the discretion in respect of publication will lie entirely in the hands of the "Transactions" committee and the presidents of sections. Each speaker opening a discussion will be limited to

30 minutes' duration, and each subsequent speaker to 10 minutes.

8. An abstract of every paper and communication must be sent to the secretary-general, 20, Hanover Square, at the latest on or before June 15, 1901.

CONTINENTAL EUROPE.

Dr. Theodore Kirchhoff has been appointed professor of psychiatrics at Kiel.

Professor Popoco has been appointed physician in ordinary to the Emperor of Russia.

Dr. Anton Prosampter, who for some time has been director of the hospital in Bozen, is dead.

Professor G. Mya, formerly professor of clinical pathology at Florence, was elected ordinary professor of pediatrics.

Professors Ehrlich and Weigert, of Frankfurt a.M., have been elected corresponding members of the Biologic Society of Paris.

Dr. A. Jentzer was elected professor of obstetrics and gynecology at Geneva, succeeding Professor M. A. Vaucher, who has resigned.

Dr. Velde, who was the German physician at Pekin during the siege, and the French physician, Dr. Matignon, have been presented with the cross of the French legion of honor.

Professor Max Verworn has been appointed ordinary professor of physiology and director of the physiologic laboratories at the University of Göttingen. He succeeds Professor Meissner.

Fiftieth Anniversary of the Wiener medicinische Wochenschrift.—With the beginning of this year the *Wiener medicinische Wochenschrift* completed the fiftieth year of its existence.

Dr. Anton Baron von Eiselsberg, professor of surgery in Königsberg, has been recommended by the Professoren Collegium as the successor of the late Professor Albert in the chair of surgery in the University of Vienna.

Dermatologic Laboratory.—On January 1, 1901, the Dermatological Laboratory connected with Professor Unna's clinic in Hamburg became an individual institution, having been considerably enlarged and improved in teaching facilities.

MISCELLANY.

A course on the therapeutics of organic diseases of the stomach has been established at the Hôpital de la Pitié, of Paris, under the charge of Dr. Albert Robin.

Capt. A. F. Stevens, I. M. S., has been appointed to the charge of the ward of the General Hospital, Calcutta, which has been fitted out for the reception of invalids from the China force.

Capt. E. R. Röst, I. M. S., civil surgeon, Meiktila, Burma, has found a microscopic germ in rice and jowari grain, and also in the rice liquor which the coolies and sepoys drink. The result of his experiments is stated to have been that beriberi is caused by this organism, which withstands a remarkably high temperature, so that it is not even always destroyed by boiling.

Isolated Ulnar Paralysis: A Contribution to the Occupation Diseases.—F. Menz (*Wiener klin. Rundschau*, 1900, No. 21) reports a case of isolated ulnar paralysis occurring in a female telephone operator. The patient, who was accustomed to rest her left elbow upon the table while holding the receiver to her ear, became affected by a paralysis of various branches of the ulnar nerve supplying the skin and muscles. [M.R.D.]

8. The Sex of Patients Suffering from Gastric Ulcer. R. DES. STAWELL.

1.—Saundby reports 2 cases of leukocythemia, 1 of which was fatal. At the postmortem examination it was found that the spleen weighed 5 pounds 3 ounces; on section it contained a few hemorrhages but no infarcts. The liver weighed 8 pounds 11 ounces and contained neither hemorrhages nor infarcts. The stomach was normal. The small intestine showed diffuse catarrh throughout 4 to 5 feet of its lower portion with patches of congestion. The salivary glands were swollen, but Peyer's patches were not affected. In several places there were what appeared to be small healed ulcers, and immediately above the cecum there was an irregular and superficial ulcer. The bone marrow of the ribs was diffuent and light brown in color, that in the tibia and radius was lymphoid and fairly firm, of a brownish color, dotted with patches of yellow. Under the microscope the marrow was extremely cellular, showing numerous myelocytes, the majority of which were finely granular oxyphiles, although some contained basophilic granules; coarsely granular oxyphiles were uncommon. There were many red nucleated blood-cells and some with dividing nuclei. Notes of 4 other cases are given. [J.M.S.]

2.—Sudden death following diphtheria has been thought to be due to neuritis of the pneumogastric nerve; but Lees is of the opinion that it is more likely due to degeneration of the cardiac muscle. The clinical indications that should be sought for to indicate the extent of this degeneration are: (1) Feebleness of the pulse wave; (2) feebleness and diffusion of the cardiac impulse; (3) extension of the cardiac dullness to the left; (4) feebleness of the first sound at the apex with accentuation of the pulmonary second sound, and (5) marked accentuation of the aortic second sound with a compressible radial pulse. In making a physical examination of the heart in these cases the exact limits of the heart should be ascertained by percussion, and the examiner should not be contented with the limits of superficial dullness. If in the case of a child suffering from diphtheria, the cardiac dullness is increased more than one finger's breadth to the left of the midclavicular line the case should be very carefully watched. If the dullness exceeds two fingers' breadths to the left of the midclavicular line the child must not be allowed to sit up in bed for any reason. The increase in dullness is sometimes very rapid, and the acute dilation thus indicated is frequently accompanied by vomiting. The cases of cardiac dilation following diphtherial infection are probably not permanent; the worst cases, however, are usually fatal. In influenza rapid dilation of the heart frequently occurs, to a greater or less extent, within a day or two after the onset of the disease, and is sometimes accompanied by fatal syncope. If the dullness extends two fingers' breadth to the left of the midclavicular line there is real danger. Minor degrees of cardiac dilation after influenza may cause a feeling of incapacity for exertion and the patient may be thought to be a

hypochondriac. In rheumatic fever, even in the most subacute attacks, acute dilation of the heart seems to be invariably present. The author has never seen a first attack of this disease in a child or in an adult, in which dilation was absent. This condition accompanying rheumatism is far less dangerous than in influenza or in diphtheria. The difference must be due to the varying effects of the several toxins on the cardiac muscle. The author makes a plea for more careful cardiac examination by percussion and palpation. [J.M.S.]

3.—Raw thinks that the **epidemic of arsenical neuritis from drinking beer** which began in June, 1900, is subsiding. The author has seen 70 cases, among which there was but 1 death. The poison was detected in the urine of 5 patients out of 33 examinations. The arsenic was undoubtedly contained in the sulfuric acid used in making the glucose which is used by the brewers. The skin lesions studied by Barendt may be divided into those resulting from a sudden debauch and those due to the daily and not immoderate use of the poisoned beer. The nervous symptoms were studied by Warrington, who found that the patients who showed the most marked symptoms of arsenic poisoning presented the least evidence of well-defined neuritis. In those who were but moderate takers of beer and stout, sensory disorders were most prominent, such as numbness, tingling, pain, and erythromelalgia. No distinctive impairment of sensation could be found, the knee-jerk was usually present, and ataxia was not noted. [J.M.S.]

4.—Littledale reports the case of a man, aged 23 years, who presented a swelling of 4 months' duration, that began between the angle of the jaw and the mastoid process of the temporal bone. The swelling extended around the back of the neck to the right side and front of the neck and thence down to the sternum. A diagnosis of **actinomycosis** was made, but the typical ray fungus was not found in the pus nor in the scrapings from the wall of the abscess-cavity during life. A second abscess developed in front of the sternum and a third at the vertebral border of the right scapula. Later, numerous abscesses formed about the back and neck. The patient died after 8 months' illness with advanced amyloid disease and symptoms of pulmonary tuberculosis. Actinomyces were demonstrated in the tissues obtained at the autopsy. The affected lung showed double infection with tuberculosis and actinomycosis. [J.M.S.]

5.—Ruffer and Creudiropoulo have found that the various toxins of the *Bacillus pyocyaneus* dialyze through the walls of collodion sacs, but not in their entirety. The time taken in the dialysis is comparatively long, and the pathogenic properties of the toxins vary according to the length of the dialysis. It is probable that the immunizing substances are among the first to dialyze, so that advantage of this property may be taken in the manufacture of vaccines. [J.M.S.]

6.—White describes a case giving typical attacks of renal colic in which were passed casts of the ureter. Microscopically they were elongated, cylindrical bodies of clear mucus held together by a few threads of fibrin and containing a few small granules and the remains of a few epithelial cells. The casts were about an inch long. The patient greatly improved under potassium iodid, but showed no improvement under the administration of the mineral acids. He thinks that possibly the irritation of the ureter may be due to an encysted renal calculus. [J.H.G.]

7.—Lawrie reports the case of a woman who suffered from repeated attacks of typical hepatic colic which were relieved absolutely by the fixation of a very movable kidney. Excepting the attacks of pain there was no evidence of the passage of gallstones, but as the patient suffered from a freely movable right kidney, it was thought advisable to resort to its fixation. [J.H.G.]

8.—Out of 7,700 autopsies Stawell found 96 records of **gastric ulcer**, 55 of which occurred in males and 41 in females. These figures seem to indicate a preponderance of cases of gastric ulcer among males; but of the entire number of autopsies recorded many more of the subjects were males than females. Comparing an equal number of necropsies on each sex the proportion seems to be 5 males to 6 females. During life the cases diagnosed gastric ulcer in males were to those so diagnosed in females as 1 to 4. Perforation seems to occur more frequently in males in the proportion of 7 to 6. [J.M.S.]

10. Reflections on Therapeutics. HARRY CAMPBELL.

1.—Bradford, in an address on the clinical varieties of Bright's disease, comes to the following conclusions: That two forms of acute Bright's disease should be recognized. On the one hand a variety in which dropsy and well-defined urinary changes are present. The urine in this form is scanty, highly albuminous, and contains blood and casts. In the other form dropsy is absent. He lays particular stress upon the fact that the last named condition is distinguished with difficulty from congestion of the kidney. He further states that in chronic Bright's disease at least two forms should be recognized. One in which dropsy becomes prominent, the urine is scanty and highly albuminous. The course of the disease is chronic and often marked by subacute attacks of uremia. In the second variety the urine is increased in amount, contains considerable albumin, and dropsy is absent. Wasting and loss of strength soon show themselves, and hypertrophy of the heart and vascular changes are present. Albuminuric retinitis is a common complication and acute uremic attacks frequently develop. He finally adds that two forms of chronic Bright's disease probably represent different effects of the same morbid condition, and that chronic Bright's disease need not be preceded by the acute form. [F.J.K.]

3.—Lewers records a series of 40 consecutive cases of vaginal hysterectomy performed for cancer. Among these 40 cases there were 14 in which the disease had not recurred up to the date of the report. Twelve of these were undoubtedly true carcinoma. The conclusions that appear to follow from a consideration of the facts in this paper are: 1. That in a certain proportion of the cases patients suffering from cancer of the uterus may be relieved by operation for periods of many years—in some cases for so long a time that there seems some probability that the relief may be permanent. 2. That the proportion of cases in which this result can be expected must remain very small, so long as patients generally seek advice only at a late stage of the disease. 3. That consequently the great desideratum is early diagnosis. Improvement in this direction depends, to some extent, on a better appreciation on the part of women themselves of the early symptoms of the disease, and especially of the significance of bleeding after the menopause, or a bleeding occurring at an earlier time of life, between the menstrual period. It is equally important to bear in mind that patients suffering from cancer of the uterus may, and generally do, for a relatively long period, look quite well. They may be well nourished or not infrequently even excessively fat. [W.A.N.D.]

4.—Collier reports an interesting case of syringomyelia which was not suspected during life because of the absence of symptoms of this condition. The patient, a man 36 years old, presented a peculiarly deformed skull, flat on top and overhanging at the sides and behind; this had existed since childhood and followed a fall which the patient had at that time. The patient, at the age of 26 years, began to have epileptic fits which started always in the right arm. At the time of admission this arm was paretic. Mr. Horsley trephined the skull over the arm-center, finding the bone thin, and

egg-shell-like plates in the dura, which was not opened. The patient died suddenly 3 hours after the operation, and from no discoverable cause. Necropsy showed a marked condition of syringomyelia. Collier remarks the not infrequent association of syringomyelia with akromegaly, but in this case he thinks the peculiar deformity of the skull was due to the injury received in childhood, since the deformity made its appearance at 5 years of age. He does not think the syringomyelia was due to injury, as the patient led an active artisan's life for 15 years, having no signs of paraplegia. Sudden death frequently follows anesthetization and operation in case of syringomyelia. [J.H.G.]

5.—Finucane states that the most common result of filariasis among the natives and Europeans in the South Seas and in Fiji is **elephantiasis of the scrotum**. He describes the operation for the relief of this condition as it is performed at the Colonial Hospital at Suva, Fiji. Chloroform is used as the anesthetic. An Esmarch's elastic tourniquet is tightly applied above the base of the pedicle, the ends are carried around, above the crest of the pelvis and fastened behind. An incision is made into the elephantoid tissue so as to free the glans penis, a No. 8 silver catheter is introduced into the urethra and an assistant holds the penis well up over the abdomen. Then on each side an incision is made which is carried downward from the external abdominal ring to the lower portion of the scrotum. The testes and the cord are carefully dissected out and held up over the abdominal wall. Two skewers are next introduced into the lower portion of the base of the tumor for the purpose of holding and preventing retraction of the tissues and to avoid slipping of the tourniquet after the mass has been separated. After removal of the tumor the vessels are ligated, the tourniquet is loosened, the skewers are withdrawn and the edges of the wound are brought together. As a rule a good scrotum can always be fashioned. Hernia complicating elephantiasis of the scrotum must always be borne in mind. Amongst Fijian women elephantoid enlargement of the arm, the leg, and the breast is very common. Children frequently suffer from lymphangitis of an extremity. He states that quinin is given in acute filarial attacks with good results. [F.J.K.]

6.—Ewart reports the case of a woman, aged 65 years, who 14 years before began to show evidences of **softening of the tibiae**. The patient came recently under his care for the treatment of a fracture through the great trochanter of the femur which occurred when the patient was walking and without any special muscular effort. The report of the case is illustrated by skiagraphs. [J.H.G.]

7.—Hanna reports a case of **cobra poisoning** treated with Calmette's antivenine. While assisting in the abstraction of poison from a full-sized cobra, the operator was bitten in the thumb. The only local treatment employed was sucking the wound. Within the course of from 20 to 30 minutes after the bite, 18 ccm. of Calmette's antivenomous serum were injected. About 2½ hours after the injection symptoms of poisoning showed themselves in slight stupor, nausea, vomiting, and some paralysis of the legs. About 3½ hours after the bite another injection of 10 ccm. was injected, and after a short while all general symptoms disappeared. Pain and swelling persisted in the thumb. A slough formed at the site of the inoculation. After 6 weeks the wound had nearly healed. The chief lesson to be learned is that sucking of the wound is of little value, and that fresh antivenomous serum should be promptly used. [F.J.K.]

8.—A case of **membranous esophagitis** is reported by Raw. The patient, a male, aged 46, was admitted into the Millroad Infirmary, Liverpool, on April 10, 1900. He complained of substernal pain and difficulty in swallowing. These symptoms had existed for six months. On admission he could only partake of liquids. He vomited a complete cast of the esophagus on April 16. This cast was 8½ inches long and weighed 2½ ounces; it was of a greenish-gray color and very tough. Microscopical examination showed that the cast was composed of a network of fibrin and epithelial cells. Vomiting soon became a symptom, and later even the swallowing of liquids was impossible on account of the severe pain. The patient was fed with nutrient enemata. On May 12, a gastrostomy was performed and the patient was now fed through the artificial orifice as well as by rectum. Progressive weakness followed the operation, and death occurred in six weeks. At the necropsy complete stenosis of the esophagus was found. Gastritis was not present. The case

was of particular interest because the condition is so very rare. [F.J.K.]

10.—Campbell in an article entitled **reflections on therapeutics** emphasizes the importance of relying upon the strength of nature in the healing art, and that nature is the great physician. He states that the young physician full of theory has this to learn. As the experienced observer grows older his methods of treatment become more simple and more and more he abides by the call of nature. In summing up the treatment of many of the acute infectious diseases, particularly croupous pneumonia and enteric fever, he lays great stress upon the fact that the most enlightened measures of treatment must be found in nature and the nurse. [F.J.K.]

New York Medical Journal.

January 19, 1901. [Vol. lxxiii, No. 3.]

1. A Peculiar Case of Migratory Foreign Body, with X-Ray Illustration. D. BRADEN KYLE.
2. Two Cases of Hemarthrosis of the Knees. RUSSELL A. HIBBS.
3. Report of Two Cases of Dermoid Cyst of the Nose. H. S. BIRKETT.
4. The Method of Examination of Infants. C. HERMAN.
5. A Case of Paroxysmal Hemoglobinuria. WILLIAM JUDSON LAMSON.
6. General Anesthesia; The Preliminary and After-Treatment, with Remarks on Chloroform and Ether. E. PAYNE PALMER.
7. Gastric Ulcer; Report of Two Cases. E. S. GOODHUE.

1.—Kyle reports an interesting case of **migratory foreign body**—a needle—which gave rise to a series of severe attacks, characterized by excruciating neuralgic pain. The site of the pain varied at times, leading to the suspicion of mastoiditis, facial neuralgia, ethmoiditis, and lastly suppuration of the maxillary sinus. Yet, when the respective attacks had subsided, all symptoms disappeared for the time. The patient suffered from periodic neuralgic attacks, from January, 1887, to August, 1899, when the last portion of the offending needle was removed, part having sloughed in an attack confined to the frontal sinus in 1898. An x-ray print cleared up the diagnosis in this case. But the patient suffered from a severe x-ray burn 24 hours after the picture was taken. An acute dermatitis of the right side of the face followed, accompanied by loss of hair in handfuls. No ill effects followed, and the hair grew on again, but only to the length of 3 inches. [T.L.C.]

2.—Hibbs describes 2 cases of periodical **hemorrhages** into the knee-joints, the patients being brothers. Two other hemophilic brothers died in infancy. [J.H.G.]

3.—Birkett reports 2 cases of **dermoid cyst** of the nose which he operated upon, and mentions a third case under his care. In each case the tumor had been observed at birth and had gradually enlarged, and each occupied the median line of the nose. Both of the cases operated upon did well. Birkett has only been able to find 6 cases reported in the literature on the subject. [J.H.G.]

4.—Herman urges the **systematic examination of children** under a physician's care—and the **throats** of those in whom infection may be anticipated. In this way personal peculiarities may be detected and we are fore-armed against regarding any peculiarity present in the child as produced by any subsequent diseased condition. He believes in making as much of an examination as possible while the child is sleeping, after being fed, and points out the value of thus securing normal **pulse** and **respiratory-rate** as well as **mean temperature**. The throat should be examined last. In a chest examination Herman recommends that the child should be held lightly in the mother's arm with the chin resting against the shoulder. For comparison a change of position to the other arm is recommended. The author uses a bimanual stethoscope. He distinguishes four varieties of cough: (1) the **simple catarrhal**; (2) the suddenly interrupted short cough, which causes pain (pleuropneumonia); (3) the croupy; and (4) the spasmodic paroxysmal (pertussis). He believes the character of the cry to be less important. Mention is made that almost all cardiac murmurs heard are organic and systolic. They are frequently transmitted posteriorly, both to right

and left, by the relatively large liver. Points in the systematic physical examination are detailed at length. The author has profited by his association with Köplik in the Good Samaritan Dispensary. [T.L.C.]

5.—Lamson reports a case of **paroxysmal hemoglobinuria** which first showed itself in the patient, a clerk of 40 years, in November, 1892, after a long, cold drive. These attacks recurred at intervals of a few weeks. He became emaciated, but his heart and kidneys were pronounced sound. Since treatment his general condition improved, but the attacks persisted. Between attacks the patient feels well, but looks anemic. A typical attack begins at 10 A.M. with a **chilly feeling** often becoming a decided rigor. The **extremities** are cold, and the fingers, nose and ears are cyanotic. He becomes icteroid, and nausea follows. He then passes urine of portwine color frequently and in considerable amount. The chill lasts from 1½ to 3 hours and is succeeded by a feverish sensation. At times an urticaria-like eruption appears in the dorsum of the hands or on the right cheek; or he may have painful areas in bridge of nose, around the right orbit, or in the groin. Normal urine is passed again, sometimes in 20 minutes, often not for several hours, depending upon how quickly he becomes thoroughly warm. The blood and urine between attacks are not characteristic of any pathological condition. During attacks the urine averages from 1.028 to 1.030. There is heavy precipitate of albumen and hyalin and coarse, granular casts. Blood is also present. The plasmodiae are not found. Favorable climatic surroundings and careful personal hygiene are, in the author's opinion, our best therapeutic measures. [T.L.C.]

6.—Palmer thinks that **anesthetization** should be given a more important place in the course of instruction in our medical colleges and that too much of the work is done by untaught and inexperienced men. He thinks the anesthetist should be as much of a specialist as a worker in any other particular department of medicine. He describes minutely the preparation necessary for an anesthetic and the ones which should govern us in the choice of the anesthetic. Where there is no choice between ether and chloroform, he prefers the latter, but remarks on its dangers in the hands of the inexperienced. He thinks in many cases where the patient is addicted to alcohol or drugs that the anesthetization should be established with chloroform and kept up with ether. This is particularly true in those cases where it is difficult to accomplish complete muscular relaxation with ether. Administration and after-treatment are carefully considered. [J.D.G.]

7.—Goodhue reports two cases of **gastric ulcer**. In his first case the woman was placed at absolute rest and fed by rectal alimentation, then as her condition grew better mouth-feeding was begun. She was pregnant six months at the time and in spite of her alarming condition, the persistent vomiting, etc., recovered and gave birth to a healthy child at term. His second case was diagnosed as abscess of the liver with localized peritonitis. At autopsy a sinuous, terraced, round, pyloric ulcer was found in size about equal to silver quarter of a dollar. The floor was formed by the left lobe of the liver where there were partial adhesions and abundant pus. There was also localized peritonitis. This was a case in which timely operation might, in the author's opinion, have saved the life of the patient. [T.L.C.]

New York Medical Record.

January 19, 1901. [Vol. 59, No. 3.]

1. The Mosquito Theory of the Transmission of Yellow Fever, with its New Developments. CHARLES FINLAY.
2. Notes on Ovarian Grafting. ROBERT T. MORRIS.
3. Case of Thrombophlebitis of the Left Sigmoid Sinus Masking a Latent Brain Abscess in the Left Temporo-Sphenoidal Lobe, both Arising from Chronic Otitis Media. CARL KOLLER.
4. Subarachnoid Cocainization in Obstetrics and Gynecology; a Report of 21 Cases. N. J. HAWLEY and F. J. TAUSSIG.
5. Important Points in the Management and Treatment of Consumption. CHARLES R. UPSON.

1.—Treated editorially.

2.—Morris gives a report of his experiments on ova-

rian grafting which were begun in 1895. His cases up to the present time number 12. He places the ovary that is to serve for a graft in a basin of physiologic saline solution at a temperature of about 100° F. immediately on its removal. In his later cases he has chosen the broad ligament as a site for grafting, and as nearly as possible at the point that the ovary would normally occupy. In his experiments the best result in ovarian grafting is the avoidance of the menopause. He has had one of pregnancy follow which was terminated by early abortion, but the several successful pregnancies that have been obtained in rabbits by other experimenters indicate that fruitful pregnancy in women as a result of ovarian grafting may yet be hoped for. [W.A.N.D.]

4.—Hawley and Taussig in discussing the subject of **subarachnoid cocainization in obstetrics and gynecology** remark that the important points in technic of operation are: 1. Surgical cleanliness in all things and a fresh aseptic solution of cocain, full strength. 2. The needle need not be longer than 7 cm. and should be kept sharpened. 3. A nurse should stand at the patient's head when the puncture is made to keep the back arched forward. 4. During the operation the patient's ears should be kept closed with cotton and the eyes covered with a towel or cloth. The authors report 21 cases so treated, 2 of which presented symptoms that were serious but did not endanger life. The most constant toxic symptom was the vomiting, which appeared in 70% of the cases, coming on within 10 minutes of the injection. Headache followed in 3 cases. A rise of temperature to 101° F. to 102° F. was observed in most of the cases 12 hours after the injection. The first stage of labor was not affected by the cocain. In 70% of the cases the pains were neither as prolonged nor as powerful. In 5 cases the cocain seemed to have a toxic effect upon the child, asphyxia being noted. [W.A.N.D.]

5.—Upson discusses points in the management of **tuberculosis**. He calls attention to the method of directing that the patient's hand be placed on the opposite shoulder which draws the scapula forward, when by placing the ear over the uncovered portion of lung, we can, if they be present, "detect the prolonged tubular breathing and fine rales on coughing; early evidence of the disease." Upson has for years given the patients suffering from tuberculosis a printed list of general directions as to the need of care to prevent spread of the infection, etc. His routine treatment includes no new points. He says he has used intrapulmonary medication with gratifying results and mentions employment of eucalyptol, pine needle oil, menthol and formic aldehyd. His method, however, is not given. [T.L.C.]

Medical News.

January 19, 1901. [Vol. lxxviii, No. 3.]

1. Conclusions Formed after 6 Years' Experience with the Antitoxin Treatment of Diphtheria. HENRY F. KOESTER.
2. Problems in the Etiology, Diagnosis and Treatment of Tuberculous Disease of the Upper Air-Passages. JONATHAN WRIGHT.
3. Notes on the Interesting Cases of a Month's Dispensary Practice. WILLIAM L. STOWELL.

1.—Henry F. Koester gives results of his **conclusions formed after 6 years' experience with the antitoxin treatment of diphtheria**. He believes in early injections of antitoxin in cases which are even suspicious. He also believes in immunizing those with whom the patient comes in contact. It is his custom to give 50 to 500 units in tenement and flat-house districts where children cannot be closely watched and where isolation cannot be practised. He has never seen any complications or sequelae follow the use of antitoxin as an immunizing agent, except in less than 10% of cases in which an urticaria-like rash appears and this is evanescent. He believes antitoxin is a specific in diphtheria when the case is in the early stages, or of a very mild form, and in these he has not found it necessary to give more than one injection. However, when the disease has advanced and putrefactive changes are present, accompanied by foul-smelling discharges, antiseptics form an important adjuvant. He employs a neutral solution of hydrogen peroxid with double or three times its volume of water. This solution should not be sprayed in the throat

but should be thrown in with a long, nozzleed hard rubber syringe holding an ounce, after depressing the tongue with some force against the pharynx so that the liquid washes, not only the tonsils, but the pharynx and posterior nares as well. This should be repeated every hour. In nasal cases he irrigates the nose with a saturated solution of boric acid. On the first day every 3 or 4 hours, without force; but after the second or third day when the membrane begins to exfoliate, a more forcible injection will often be of service in detaching membrane which has been only partly separated. Care should be taken that nothing is forced into the eustachian tube. This is avoided by instructing the patient to keep the mouth open. In very young children it is necessary to accomplish by means of a gag. The internal treatment is very simple. He combines strychnin with essence of pepsin, or some other vehicle. The tincture of the chlorid of iron and chlorid of potash he condemns strongly, and believes that alcoholic stimulants are indicated in only very severe cases. In convalescents he administers the syrup of the iodine of iron preferably. He condemns calomel sublimation, believing that it is productive of salivation and it renders the patients more liable to complications. He does not advocate steam inhalations on account of the fact that to be effective, the windows and doors of the rooms must be closed and a free supply of oxygen shut off. He explains the urticaria-like rash on the ground that the blood already surcharged with the toxins and effete products of the diseased condition has reached its point of saturation as far as the eliminative action of the kidneys and excretory apparatus are concerned. Upon adding to the blood, already surcharged with these products, a certain amount of horse serum also containing hippuric acid and other excrementitious products, the urticaria follows. [T.L.C.]

2.—Jonathan Wright concurs in the opinion that a susceptibility is always associated with infection in tuberculosis. The presence of the organisms upon healthy and diseased mucous membranes without infection occurring is frequent. He denies that the tubercle bacilli are ever the cause of large tonsils and adenoids. From a total sum of nearly 1,000 specimens of tonsils and adenoids examined, the ratio of 5% has been deducted as the proportion of **latent tuberculosis** in them. In examining the air-tract in order to arrange the anatomical localities in the order of frequency of development of tuberculous disease, we find it proceeds pretty regularly from the walls of the bronchi, and the air vesicles to the nose, the larynx being perhaps more frequently involved than the trachea or larger bronchi, on account of its greater mobility and the complexity of its gross anatomy. Discussing the diagnosis he emphasizes 3 points: (1) The diagnosis of incipient laryngeal tuberculosis; (2) the differential diagnosis of **tuberculous from syphilitic laryngitis** and these include (3) the microscopic examination of the sputum. 1. The patient may come with much less marked local symptoms than in the secondary catarrhal laryngitis, and yet have in his larynx the unmistakable evidence of tuberculous disease in its incipency. Inspection reveals in addition to the pale larynx and velum palati, so suggestive of pulmonary phthisis, one which is congested only in spots. There is a heaping up of proliferated epithelium on the posterior wall—the pachydermia laryngis. These appearances, however, are merely suggestive, and not confirmatory of tuberculous laryngitis. We must have, in addition, some local infiltration or ulceration to render this a probability. We cannot be certain of the diagnosis until we have excluded syphilis and found the tubercle-bacilli. 2. Syphilis of the larynx is not a common occurrence in his experience. Syphilis of the lungs he has even observed. A mistake in the two conditions is the more distressing from the fact that **laryngeal syphilis** is usually easily curable, but with the same treatment that is used in **laryngeal tuberculosis** it is almost as fatal as the latter. With a history of syphilis and scar-tissue in the pharynx, or on the epiglottis with a peculiar sharp-cut seriginous ulceration, characteristic of syphilis of the mucous membrane, the diagnosis is easily made, but in many cases the two conditions present strikingly similar appearances. The promptness and suddenness with which laryngeal stenosis in syphilis may occur is a differential diagnostic point which is frequently neglected. The author closes with a commendable conservative criticism as to methods of palliation and cure. [T.L.C.]

7. Remarks. HENRY P. WALCOTT.
8. Letter. S. WEIR MITCHELL.
9. The X ray. WILLIAMS.

9.—Williams' experience at the Boston City Hospital indicates that we have, either in the **x-rays** themselves or from some other form of radiation from an excited Crookes' tube, a valuable therapeutic agent in **epithelioma** and that the beneficent action of the x-rays can be brought about without causing a burn. Without causing pain, the application of the x-rays is followed by a cessation of foul and nearly unbearable odors, a lessening of the discharge and a diminution of the size of the growth. The earlier the treatment is undertaken the better. It is not improbable that we shall find its curative action limited to superficial growths, though as a means of relieving the painful features of the disease in other forms, it may be of some use. [Details of the application are promised. J.M.S.]

9. Costa Rica, Its Physicians and Medical Institutions. N. SENN.

1.—After a careful investigation of his last 700 cases, Reber believes that it is impossible to determine what lenses are to be prescribed in ametropia unless a thorough knowledge of the performance of the muscular function is obtained. He has found that the addition of a vertical prism to the patient's curvature correction has often been fruitful of relief. The author considers the Maddox rod of great value in these cases. Hyperphoria occurs in about one sixth of the patients, but only becomes worthy of special notice in one-fifth of the refraction cases. In 33% of all cases it becomes more manifest after the thirtieth year. **Correction with prisms** is of service in about 50% of all the cases. Exercising insufficient convergence and repressing an excess of convergence often bring about relief of the symptoms which frequently are neuralgia, photophobia and physical tiredness after continuous near work, the latter symptom generally being in disproportion to the amount of work done. As a last resort tenotomy of one of the vertical muscles will have to be performed. [M.R.D.]

2.—Carpenter, in discussing the **ocular complications of injuries to the head**, other than those directly produced upon the eyeballs, reports a case of optic atrophy occurring in a man who was thrown to the ground striking the right side of his head. Dimness of vision set in 10 days after the accident. The case was diagnosed as a **descending neuritis** originating from a localized traumatic meningitis at the base of the brain and involving the optic nerve. Four years after the accident the vision

was $\frac{10}{20}$, good peripheral visual field, and an **absolute central scotoma**. [M.R.D.]

3.—Mays advocates the **use of silver nitrate injections** in the neck along the course of the pneumogastric nerves in pulmonary consumption. He advocates the use of a 2½% solution in 5 minim doses, the injections being repeated every 7 or 10 days, and in urgent cases every 3 or 4 days. The highest number of injections given in a single case was 21. In reviewing the results of this treatment he finds that 50% of the patients treated were practically well at the end of a year and a half. He concludes his article by giving the report of a number of cases. [F.J.K.]

4.—Lemke recommends the use of **intrapleural injections of nitrogen** in the treatment of tuberculosis of the lungs, stating that after compression of the lungs fibroid changes develop. This cicatrization assists nature in the healing of the tubercle. Cavities, if present, are compressed and healing is favored, and by the rest the organ receives by this method of treatment secondary infection and a lesser tendency to hemorrhage is brought about. Pleural adhesions are not so extensive as might be expected, and he further states that after long compression the healthy portion of the lung may again expand when intrapleural pressure is removed. The risk of the operation is very slight. He concludes by saying that this treatment is curative in some cases and palliative in others, prolonging life for some time. This treatment is also of value just prior to surgical operation when the pleural cavity is to be opened. [F.J.K.]

5.—**Angina epiglottidea anterior** is discussed by Theisen with a report of three cases. He describes the condition as being an inflammatory process accompanied by edema and confined to the anterior surface of the epiglottis. The inflammation may extend by way of the submucous tissue of the pharyngo-epiglottic ligament to the aryepiglottic folds. He prefers the name of acute epiglottitis or simple epiglottitis to angina epiglottidea anterior. The condition is often primary in the course of an infectious disease, but may be secondary. In the three cases he reported the onset was sudden, with fever, and other manifestations of an acute infection. The local symptoms were difficulty in swallowing, severe pain in the throat, and upon examination the anterior surface of the epiglottis was found red and swollen. Inoculations taken from the serum of the deeper tissues of the epiglottis revealed cultures of the *Staphylococcus albus* and *pneumococcus* in one case, and the *streptococcus* and *pneumococcus* in the other. In the remaining case the bacteriological examination was not made. As to treatment, he recommends early scarifications and the use of iced ichthyol sprays. [F.J.K.]

6.—Will be considered editorially.

7.—Zimmermann, in discussing the relation of visual acuity to the degree of illumination, calls attention to the necessity of **light and seating in the school**. If there is a lessening in illumination the pupil will have to bring the book nearer to his eye so that both visual angle and retinal image become larger. The increased amount of accommodation and convergence necessarily called into play causes strain and congestion of the eyes. If the head is bent in order to facilitate the continuation of the pupils' work, there may follow a compression of the vessels in the neck and a retardation of the venous blood. The photometer devised by L. Weber, of Breslau, permits a rapid determination of the amount of the illumination present in the school-room during the day. The unit of light intensity in this case is the **meter-candle** which equals the illumination of a sheet of paper one meter distant from a candle composed of stearine, 6 of such candles being required to weigh 1 pound. The light from the sky reflected from the ceiling is considered to be the best. In the lower stories of the schoolroom, where light cannot be obtained from above, it is best to have the pupils seated so that the windows are on their left, thereby preventing the formation of a shadow from the hand. The tint of the walls is to be light gray. The author discusses the various experiments that have been made regarding the formulation in mathematical terms of the definite law that exists between sight and light intensity. Next to light the most important hygienic principle that demands the attention of school legislation is the **correct seating of the pupils**. It has been shown by laws of physics that the body is only comfortable in a sitting posture when the point of gravity which lies in front of the tenth chest

vertebra forms a perpendicular to a line drawn through the tuberosities of the ischia, the latter being the rotation points of the trunk. The distance between the desk and seat must be in such relation to the pupil that when in the erect position the eyes remain 40 cm. from the desk. The author believes that although the best constructed seats cannot always obviate faulty positions of the students, nevertheless the observation of the hygienic principles mentioned will serve to prevent many ocular defects. [M.R.D.]

1.—Southworth reports the case of a baby in whom **congenital pyloric stenosis** was diagnosed for the following reasons: 1. The early occurrence and persistence of vomiting uninfluenced by the usual measures for its relief. 2. The absence of any vestige of milk residue in the stools until the ninth day, while the presence of green mucous stools excluded obstruction below the duodenum. 3. Perfect digestion of the milk residue when it appeared in small quantities in the stools, despite the continuance of the vomiting, which seemed to preclude the possibility that that symptom was due to indigestion. 4. The absence of constipation, temperature, or any other symptom on the part of the mother that might cause her milk to disagree with the baby; maternal anxiety was not awakened until long after the inception of the vomiting. Two years before the mother had successfully nursed her first child. 5. The abrupt cessation of the vomiting, which pointed to a sudden relief of the exciting cause. The complete cessation of vomiting and subsequent absence of unfavorable symptoms are in support of the view that the pyloric stenosis was functional and dependent upon the condition of the pyloric valve. [J.M.S.]

2.—Snow reports 3 cases of **retropharyngeal abscess and adenitis**. In the first case, at the age of one month the baby had an acute feverish illness with profuse nasal secretion; after a few days the fever subsided and the nasal discharge lessened, although much pus with blood crusts still came out of the nose. At the age of two months the bloody purulent coryza persisted. Examination at that time showed, about the level of the epiglottis, projecting forward from the posterior pharynx, in the median line, a pyramidal swelling whose apex encroached upon the entrance to the esophagus. The mass was hard, not movable or fluctuating, and was evidently an enlarged retropharyngeal lymph node, a result of the intense rhinitis. Under proper local treatment the coryza rapidly ameliorated and in two weeks the child was well. At the end of two months exploration of the throat showed that the swelling had entirely disappeared. The second patient was a boy of 16 months, who suffered from an attack of influenza. His head was held stiffly erect and there was difficulty in swallowing and obstructed snoring, breathing, especially at night. The left tonsil was swollen and a fluctuating swelling lay behind it. The abscess was first aspirated and afterward incised and evacuated. The child continued feverish and languid and was attacked by a severe ileocolitis lasting 12 days. The recovery was slow; the neck muscles were rigid; pressure on the top of the head caused acute pain, giving rise to a suspicion of cervical caries; the throat was clear; and there was no tenderness or prominence of the cervical vertebrae. The retropharyngeal abscess and the continued fever and ileocolitis were probably caused by a streptococcus infection. The pain and rigidity of the neck muscles were attributed to a synovitis of the cervical vertebrae, also from a streptococcus infection. In the third case the patient was a boy of 15 months who had pharyngitis and tonsillitis. The cervical lymph-nodes became enlarged and

one evening an alarming attack of dyspnea developed which, however, was not attended by cyanosis. There was no inspiratory recession of the chest. A large fluctuating swelling was found in the posterior pharynx. A mouth gag was introduced for a thorough examination of the throat and to aspirate the swelling. The baby suddenly became livid, stopped breathing, and died. The swelling behind seemed to narrow the lumen of the trachea. An autopsy was refused, but by examining the throat it was shown that the abscess extended deep into the pharynx, so that only the upper portion could be reached by the finger. The introduction of the gag stretched the jaws and pressed the root of the tongue back against the pharyngeal swelling. It is probable that death was due to disturbance of the vagus. [J.M.S.]

3.—Fischer reports the case of a girl 12½ years old. When 4 years old the child had measles and chicken-pox. Following this attack, the urine became thick and cloudy; the child had fever and chills, but never vomited. When seen by the author, the patient proved to be a very poorly nourished, constipated child, with a sallow complexion and flabby muscles. Anorexia and general apathy were present. She complained of abdominal pains, mostly on her right side in the hypochondriac and iliac regions, the pain being constant and increased on palpation. On examination a large tumor was seen and easily felt on the right side of the abdomen. The urine contained large quantities of albumin, casts, blood, and leukocytes. At no time could pus be found in the urine. The temperature range from 100° to 103°. The patient was operated upon, and the tumor was found to be of kidney origin. The peculiar lobulated kidney-tumor was peeled from its bed without much difficulty. The tissue was so friable that it was removed piecemeal, and, in breaking into the pelvis, about a teacupful of pus and sandy concretions were removed. The renal vessels, both artery and vein, were destroyed, so that insignificant bleeding occurred. The following is an abstract of the pathologic report: The pelvis was a large pus sac containing many small calcareous particles. Stained specimens did not show organisms. The kidney tissue proper was the seat of numerous small abscesses, and here and there remnants of the kidney tissue showed a chronic interstitial nephritis. The case was one of **pyelonephritis** with chronic interstitial nephritis. The patient recovered, and 3 months after the operation the child was found perfectly well. [J.M.S.]

4.—See editorial columns PHILADELPHIA MEDICAL JOURNAL, Vol. VII, p. 91.

5.—In **acute rheumatic fever in children** there is less liability to joint involvement than in adults and it may be altogether absent. Sometimes the only evidence of a joint implication is the subjective symptom of pain complained of by the child, the so-called "growing pains." At other times when the joint is involved the anatomic changes are not so severe as in adults, there being less exudation and fewer structural changes of the joint and the surrounding tissues and, therefore, less pyrexia. On the other hand, strange to say, there is in childhood a greater tendency to metastasis of the microorganism and their toxins leading to an involvement of other tissues and serous membranes and even the skin. We, therefore, have as a frequent accompaniment or a manifestation of the diseased joints, a torticollis, an erythema nodosum, a purpura rheumatica, a chorea, an endocarditis, a pericarditis, a myocarditis, or a formation of tendinous nodules. Heiman has seldom found the pleura involved in children under 4 years of age. Endocarditis is the complication most frequently present in childhood. Peptonuria is a frequent condition found in acute rheumatic fever in children. This is probably caused by an abundant destruction of the leukocytes with an absorption of their peptones. Rheumatic fever is very rare in children under 3 years of age, although there are some authentic cases reported. It is well to remember that the majority of cases of joint disease in children under 1 year of age are really manifestations of scurvy. The indications for the treatment of this disease are: 1. To combat the poison. 2. To alleviate the symptoms. 3. To prevent involvement of the heart, and to prevent recurrences. The best method of counteracting the poison is by the salicylates. In acute rheumatic fever, the author administers the salicylates prophylactically. After the acute local and constitutional symptoms have subsided and the patient is to all intents and purposes apparently cured, the administration of the salicylates is continued in 3

or 5 grain doses 3 times daily, according to age, for 1 week of each month for a year or more. [J.M.S.]

6.—Stone reports the case of a boy aged 3 years and 8 months, in whom there was no history of previous malarial attacks. The child lived in a malarial district and his father, mother, and an older brother had had malaria. In the course of his illness the patient became comatose and a diagnosis of **malarial coma** was made. The blood contained the malarial organisms; recovery was complete. [J.M.S.]

7. Medical Men of Letters—Oliver Wendell Holmes.

1.—Newsholme has made a thorough study of the statistics of **rheumatic fever**. He concludes that these statistics show two kinds of **epidemics**, which he designates as **explosive** and **protracted**. The explosive epidemics terminate in one, or at the utmost three years. The protracted epidemics are observed chiefly in large centers of population, or when we are studying the statistics of an entire country. These may represent the fusion of two or more explosive epidemics which do not exactly coincide with each other in point of time. He finds there are certain favorite years for epidemics. Thus, in England these are 1855-6, 1859, 1864-5, 1868-71, 1874-6, 1884-5, 1888, and 1893. In other countries the same years are frequently characterized by epidemics, but in some instances there is an anticipation of or lagging behind the favorite years for England. While there is no regular periodicity in the epidemic years, epidemics are apt to recur at intervals of 3, 4, or 6 years. There is in many instances a regular alternation between the explosive and the protracted epidemics, two of the shorter and smaller epidemics commonly occurring before the return of an epidemic of the protracted variety. The occurrence of definite epidemics is valuable confirmatory evidence that **rheumatic fever** partakes of an **infectious character**. The infectious nature of the disease is also confirmed by its mode of onset, the frequent occurrence of preliminary sore throat, and the course of the fever. The apparent absence of infection from person to person is explicable on the ground that the contagium is buried deep in the infected joints. The specific action of **salicin** is also comparable to that of quinin in malaria and mercury in syphilis. There is important evidence that the infection of rheumatic fever may cling about certain houses in a manner strikingly like that of tuberculosis and diphtheria. The susceptible population is not attacked at the same time, which may be explained upon the ground of the gradual convection from place to place. The disease is probably **ubiquitous**. **Four** out of every **thousand** persons are annually attacked by **rheumatic fever**. It is essentially an **urban** rather than a **rural disease**. Newsholme concludes that the disease is essentially a **soil disease**, due to a **saprophytic soil organism** which is drowned out in wet years, and multiplies rapidly in dry years. Possibly dust convection accounts for a large percentage of the cases. The inoculation may be brought about by domestic vermin, or the house-fly may convey it to milk and other foods. The important observation that dry years favor the causation of rheumatic fever, rather than wet years, seems borne out by facts. [T.L.C.]

2.—**Rheumatic fever** being preeminently a disease of childhood it becomes essential that the pathology of the disease must explain the manifestations which are met with in the young. The cardinal lesions, such as endo- and pericarditis and nodule formation, are strikingly comparable to each other. Each shows a destructive and reparative process, in none does suppuration occur. The changes are suggestive of a specific cause and analogous to the metastasis of pyogenic infections. The lesions found are characterized in the human tissues by great local resistance and a tendency

to recovery. Poynton gives a resumé of the theories of the pathology of rheumatic fever. He mentions Cullen's theory that the condition is a direct result of **cold** upon the joints—now untenable—and J. K. Mitchell's nervous theory. Poynton believes that the nervous theory exaggerates the importance of the influence of the nervous system upon other organs of the body and there is no proof that carditis, pleurisy and subcutaneous nodules can result from lesions of the nervous system. The **toxemic theory** implies that the cause of the disease is some poison circulating in the blood. It has led to **three** distinct conceptions: (1) the **chemical theory**; (2) the **neurochemical** and (3) the **infectious theory**. The **chemical theory** explains the causation of the disease on the ground that **lactic acid** is the offending material; other authorities claim that **uric acid** is responsible. To both of these theories Poynton advances the objection that the proof that these acids are in excess in the blood-tissues or the sweat-secretion of rheumatic fever is insufficient, and we are not certain that the typical lesions may be produced by either or both of these factors. It is true, beyond question, however, that Richardson, in 1853, and other observers after him, obtained the clinical picture of rheumatism by the injection of a 10% solution of lactic acid. The clinical picture of rheumatism favors greatly the infectious theory. This is well borne out by the pathology of the disease and the researches which tend to prove its epidemiology. While there are certain features of resemblance between **malaria** and **rheumatic fever**, the local inflammations of the joints and viscera of rheumatism are unlike malaria and the blood examinations are totally dissimilar. The other important views on the nature of the infection are respectively: (1) that there is no specific microorganism, but the disease is a form of septicemia which owes its origin to staphylococcal or streptococcal infection; (2) that the infection is necessarily symbiotic; (3) that the microorganism is a specific bacillus; (4) that the microorganism is a specific diplococcus. The first two of these views have hosts of supporters and in our present state of bacteriological knowledge the question remains an open one. The symbiotic nature of the infection has been advanced because cocci have been so frequently found in rheumatic lesions which are not specific. A specific anaerobic bacillus has been isolated by **Alchalmé** and others. A **diplococcus** has also been isolated by several observers, including the author in association with **Paine**. They have isolated these from the blood, urine and tonsils in patients ill of **rheumatic fever** and in the postmortem lesions of the condition. By a series of carefully conducted experiments they have been able to produce by intravenous inoculation into rabbits, polyarthritis, valvulitis, pericarditis, chorea and nodules. They have been found in these lesions in rabbits, and in both rabbits and man circulate in the blood during an attack of pericarditis. The authors report of the great difficulty of recognition of the organisms, apart from their small size and the question of technic; it is on account of the fact that the disease is rarely fatal early and the organisms are rapidly destroyed in these lesions. Poynton suggests a possible explanation of the rheumatic recurrences by the persistence of a single coccal form which survives after the disappearance of the diplococcus. [T.L.C.]

3.—In a considerable number of cases of **rheumatic fever** the poison enters the system through the tonsils, the inflammation of which may be the earliest indication of the systemic infection. The second is that certain inflammations of the tonsil occur with greater frequency in patients with an arthritic diathesis. There are two varieties of rheumatic sore throat—faucial erythema and tonsillitis proper. Faucial erythema is more common in adults; rheumatic tonsillitis in children, in whom it usually assumes the follicular type. Quinsy being more common in older subjects. Faucial erythema is an initial manifestation of acute rheumatism. Tonsillitis may be the actual primary lesion. We know that endocarditis has followed a nonscarlatinal tonsillitis unaccompanied by joint pains. In other cases the tonsillitis has immediately preceded an attack of arthritis or of chorea. Tonsillitis may also occur during as well as at the beginning of a prolonged rheumatic attack. We can prove no causative relation between peritonsillar abscess and rheumatism. It has been stated that one-third of all cases of pharyngitis and tonsillitis are due to the rheumatic taint, but the author

thinks this percentage too high and believes that many are secondary to purulent affections of the nose, or catarrhal conditions of the stomach. The theory that amygdalitis is chiefly predisposed to by the rheumatic diathesis is not without its opponents. Especially is it pointed out that recurring angina is rare in those or an acute attack of rheumatism—that later in life the tonsils become less and less subject to inflammation, while the tendency to rheumatic conditions gradually increases. The salicylates are not specific against tonsillitis. The author concludes: 1. That 30 to 80% of cases of acute rheumatism are preceded by an angina. 2. That both conditions have many etiologic points in common—season of the year, cold, wet, fatigue, depression, vitiated air, etc. 3. The connection of **angina** and **rheumatism**, though undoubted in a number of cases, is not yet clearly established. 4. The tonsils may be the points of entry of the rheumatic virus, and this even although the naked-eye appearance of the throat gives no indication of its being affected. 5. The particular affection of the throat which is associated with rheumatism is not yet established. Apparently it is not peritonsillar abscess (quinsy). 6. Peritonsillar inflammation does not appear to be arrested by the antirheumatic remedies. Many cases of parenchymatous and lacunar tonsillitis, on the other hand, are considerably benefited by such treatment. 7. The question requires further research in two directions: One in differentiating the various forms of angina and determining the one which is associated with rheumatism; the other to discover the true nature of rheumatism itself. Thomson points out the frequent inflammatory conditions of the naso- and oropharynx in their association with rheumatism and the condition of **granular pharyngitis** with arthritism. Operations on the nose have been followed by angina; and this in turn by an attack of rheumatism. In many cases, also, there may occur an acute inflammation in the cricoarytenoid joint. This may be mistaken for paralysis of the recurrent laryngeal nerve, but may be differentiated by the following signs: (1) Dysphagia; (2) painful cough; (3) occasional tumefaction over the arytenoid; (4) sharp pain on pressure along the posterior border of the thyroid cartilage; (5) the healthy arytenoid is not tilted forward into the affected one, and the healthy cord does not during adduction pass across the median line toward the other side. In addition, this affection of the cricoarytenoid joint is usually associated with (a) the existence or preexistence of an acute pharyngeal catarrh; (b) laryngeal hyperemia; (c) a more or less pronounced feverish condition; and (d) extralaryngeal manifestations of arthritism. [T.L.C.]

4.—Gibson considers the **method of production** and the nature of the **cardiac lesions** of rheumatism. Endocarditis of the aortic cusps must have been due to the poisons circulating in the blood flowing over the surface of the cusps. For while the pericardium is a highly vascular membrane, for the myocardium, which is almost like a sponge, in the endocardium, however, the valves differ in respect of their vascularity. While the great venous valves of the heart are freely supplied with bloodvessels, the cusps guarding the arterial orifices are destitute of them, unless some previous lesion has led to their formation. There is no doubt that the cells of the serous membranes of the heart are endowed with a phagocytic power and while exercising their protective power these endothelial cells may suffer and **endo- or peri-carditis** be developed. The classic experiments of wounding the valves with a sterilized instrument and no endocarditis resulting, and of introducing pyogenic organisms by way of the bloodstream, and the consequent development of **endocarditis** are mentioned. The terminations of acute pericarditis may be perfect resolution, but "milk spots" (the maculae tendinae) are frequently left. These are due to a thickening upon the epicardium. Adhesions between the two layers also occur frequently. The first morbid appearance in the development of acute endocardial lesions is the invasion of the endothelial layers by the bacteria (owing probably to the phagocytic activity of the endothelial cells). Retrogressive changes in these cells lead to the deposit, on the affected surface, of fibrin, corpuscles, and platelets. In this way the early phases of the vegetations are brought about. Then follows a gradual fibrous change, which may at length show fatty or calcareous degeneration. In **acute myocarditis** we have a variable picture, but, in general, the tissues are thickened, softened, and deeply tinted. Microscopically, the

fibers are swollen, the transverse striation almost entirely obliterated, and the interstitial tissue contains leukocytes, hemocytes, and proliferating cells. Later, the fibers are granular, and the interstitial substances show much cellular invasion, or, on the other hand, reveal newly-formed fibrous elements. As to treatment of rheumatic fever, with a view to obviate implication of the heart, absolute rest is essential in the horizontal position. The diet must be abundantly fluid, to bathe the tissues thoroughly. Milk is the best food, but, as time goes on, soups, farinaceous foods, and the lighter forms of meats may be added judiciously. As to drugs, the salicyl compounds seem to lessen the likelihood of cardiac involvement, but they must be begun early, and taken in large doses, and for a long period. When the general symptoms have entirely disappeared, **iodid of sodium** is most satisfactory. It is to be taken in 10- or 15-grain doses 3 times a day, and kept up for several weeks. He advises that digitalis or strophanthus be administered during the attack to maintain the heart's activity, and that an occasional mercurial purge is of advantage. It is difficult to explain the favorable action of **counterirritation** in this condition, but it is an excellent adjuvant to the other treatment, notably, in cases of mitral rather than aortic valvular infection (due, probably, to the fact that the aortic cusps are without bloodvessels). The author recommends, with Caton, small fly-blisters over the precordia every night, or every other night. [T.L.C.]

5.—In childhood the articular phenomena of rheumatism are of secondary importance. There are cases in which the child has never had a pain in his joints, and yet may present a severe type of endocarditis, and of which cases the rheumatic nature is confirmed by the presence of nodules. It is well-known that joint symptoms in a child are so slight at times that parents are apt to dismiss the complaints with the comforting assurance that they are "**only growing pains.**" It would be fallacious to attempt to determine the number of cases of rheumatism in childhood were these estimated by the joint affections alone. Heart affections may apparently occur alone as the earliest symptom. We must not neglect the undoubted relation between **chorea** and **rheumatism**. Our statistics err in frequently classing as **chorea** only those cases in which there is an association with rheumatism. This author has found that 55.7% of cases which come under treatment for chorea showed positive evidence of rheumatism. These cases, commonly regarded as chorea only, have probably accounted in part for the statement that rheumatism is a disease of adolescents and adults rather than of children. Rheumatism, from a study of the hospital cases made by the author, is a common disease in the later period of childhood, rare in early childhood, and almost unknown in infancy. The slight articular pain frequently complained of by children often will reveal a real affection of the joint. It is important to remember that the hip-joint is frequently affected, and in such a monarticular case the mistaken diagnosis of beginning tuberculous disease might well be made. Pain from the hip, as is often emphasized, may be referred to the knee. In childhood, dilation as well as irregularity and rapidity of the heart may occur without endocardial symptoms. Wasting is also common in this affection in childhood. **Nodules** are much more common in rheumatism in childhood than in adults. The author found them present in 27.5%. There is a close association between these **nodules** and **endocarditis**. There is one result of rheumatism in adults which is almost unknown in childhood, and that is the **cerebral rheumatism** or **rheumatic hyperpyrexia**. Pain in the stomach, pain in the side, usually the lower portion of one axilla, and headache are common symptoms. The nervous child is par excellence the rheumatic child. Such children are apt to be excessively emotional, or, on the other hand, very timid and shy, even to the point of appearing morbid. The author suggests that red hair is often associated, both in children and adults, with the rheumatic tendency. Somnambulism and talking in the sleep, and habit spasms are also evident in rheumatic children. The author points out lastly the importance of paying heed to the trivial symptoms, recognizing, for instance, the serious nature of "growing pains." By this means alone will early recognition of rheumatic disease be possible and many cardiac cases prevented altogether, or at least have their dread course greatly modified. [T.L.C.]

6.—Maclagen introduced the **salicyl compounds** in the treatment of rheumatism in 1874, and this was followed later by the employment in Germany of salicylic acid. These drugs rapidly relieve the pain and reduce the temperature if administered in sufficient quantity. With regard to the action of the salicylates it has been urged that: (1) They act as antiseptics, and destroy the specific organism; (2) that they exert an antitoxic action, and (3) that they act as nerve sedatives. It appears probable that they must exert a depressant action upon the heart before they can be introduced in sufficient quantities to saturate the blood up to the necessary point. With regard to the second view they may destroy or neutralize the offending toxin. It is true that they are powerful hepatic stimulants, and that they also possess the power of combining with fatty acids, the seat of whose manufacture is to a great extent in the liver. It may be that one of the toxins of rheumatic fever is a fatty acid which is seized upon and removed by the salicylate. A decided advantage possessed by the salicylates is that they produce sweating. In treating a case of rheumatic fever, the patient should wear a woolen night gown and sleep between blankets. The room should be well ventilated. Absolute and prolonged rest is essential, especially with the view of preventing cardiac complications. The diet should be fluid, largely milk, and plenty of water should be taken. As to drugs, 20 grains of soda salicylate and 30 grains of an alkaline carbonate should be given every 2 hours until the pain is relieved and the patient is fully under the influence of the drug, when it should be given every 4 hours until the temperature has fallen to normal. Afterwards, 15 grains of the salicylate and 20 grains of the alkaline carbonate are given every 4 hours until all the joint symptoms have disappeared; then 3 times a day until a fortnight has elapsed from the complete disappearance of the joint symptoms. The natural salt rather than the artificially prepared soda salicylate is recommended. By a free movement of the bowels at the outset by a saline or mercurial, the effects of salicism are largely prevented. Salicin, recommended as being less of a cardiac depressant, is sometimes useful instead of the salicylate. The painful joints may be blistered, or be wrapped in a salicylate of methyl preparation, and the air excluded. It is important to keep up the treatment long enough. Many so-called relapses are really recrudescences of a disease not yet terminated. For endo- and pericardial affections, local blisters are recommended, and stimulants when indicated. Hyperpyrexia is best treated by cold baths. The author recommends the water should be at 65° F., and ice added as the temperature of the water rises, when the patient is submerged. Occasional courses of the salicylates are useful in patients having slight recurrences. A largely vegetarian diet is recommended, and careful personal and general hygiene. [T.L.C.]

8. The Duration of Yeast Formation in Sugar-containing Urine. THEODOR LOHNSTEIN.

1.—Meinert and others maintain that **gastroptosis** is one of the characteristic features of **chlorosis**, but in 50 cases examined by Rostoski gastroptosis was present in only 26%. The influence of the early use of the **corset** was distinctly demonstrable in a large proportion of the cases suffering from gastroptosis; indeed, all of them had begun to wear corsets before the fourteenth or fifteenth year. It is also pointed out that the distention of the stomach with gas is not entirely reliable as a method of determining the posi-

tion and size of that organ, as the intestinal coils, especially the transverse colon, may when distended simulate the stomach. This is particularly the case when the abdominal walls are tense; in relaxed abdominal walls the outline of the stomach is more or less clearly visible. [D.R.]

2.—A case of **purpura hemorrhagica** in a man of 26 years, coming on without any ascertainable cause. There were hemorrhages into the skin and from the mucous membranes, and at autopsy extensive ecchymoses were found in the internal organs. In addition there were endocarditis of the mitral and aortic valves, and an abnormally small aorta. Bacteriologic examination of the blood during life yielded *Staphylococcus aureus*. [D.R.]

4.—Hennemann reports a case of cured **spina bifida**. The deformity was represented by a tumor, situated on the sacrum, small at birth but rapidly increasing in size afterwards. The growth was treated by injecting under absolute aseptic technic a small quantity of Lugol's solution, after the contents of the sac had been withdrawn by aspiration. Eight days later the tumor had reappeared to such an extent that aspiration withdrew 350 ccm. of cerebrospinal fluid, tinged yellow by iodine. A second injection of the iodine solution was carried out, and the third was also required. Eight days after the third injection the tumor was about the size of a pear, and the child rapidly regained its normal functions. [G.B.W.]

5.—Müller reports a case of **habitual luxation of the shoulder joint**, occurring in a patient, 28 years of age. The shoulder was easily dislocated on the slightest provocation, but only with difficulty replaced. The operation was undertaken at the urgent request of the patient. After the joint had been freely opened in front and from the axilla, no tear of the capsule could be found or any effusion into the joint, and other anomalous conditions of the bony parts were also absent. The capsule, however, was found markedly dilated, so that the head of the humerus was easily displaced. The capsule was shortened by excising a portion some 4 cm. long and 1½ cm. in breadth and suturing the severed edges together. Five months later the patient had perfect use of his arm and had no return of his former trouble. [G.B.W.]

6.—Coal-oil has long been a home remedy for **diphtheria**, and has also been employed by the profession, particularly in America. Papasotirin has studied its influence upon the **diphtheria bacillus** in cultures, and finds that it has **no inhibitory action** whatever. [D.R.]

8.—Lohnstein contends against Meyer that the **fermentation test** for sugar is complete in from 8 to 12 hours at room temperature, Meyer having maintained that from 24 to 48 hours were necessary. [D.R.]

October 9, 1900. [47. Jahrg., No. 41.]

1. Idiopathic Enlargement of the Heart and Its Relation to Military Service. v. ZIEMSEN.
2. Report of Xerosis Bacillus in Spreading Phlegmon, Secondary to Wound Infection and Otitis Interna. WARNECKE.
3. Abscess Following Pneumonia with the Diplococcus of Pneumonia in Pure Culture. ROGET.
4. A Case of Acute Formalin-Poisoning. J. KLÜBER.
5. A Causeless (?) Case of Hysterical Fever. E. WORMSER.
6. The Present Standpoint of the Therapy of Chronic Suppuration of the Middle Ear and the Formation of Cholesteatoma. ERNST LEUTERT.

1.—An interesting discussion of **idiopathic enlargement of the heart and its relation to service in the army**. The causes usually assigned for acute cardiac dilation are overexertion and the abuse of alcohol. The author does not believe that alcohol plays the role imputed to it. More important than either of the causes given are disturbances of respiration, which are brought about by the highly improper uniform worn by soldiers (tight collars and close-fitting coats), and the carrying of heavy accoutrements, etc. To these are added in time of war insufficient food, psychic influences, and nervous shocks. In some soldiers there is also congenital weakness of the heart-muscle. The most frequent causes of cardiac weakness in time of peace are acute **infectious diseases**, particularly influenza and articular rheumatism. All the causes bringing about dilation have in common one factor: they produce an increase in arterial pressure. [D.R.]

2.—Warnecke found the **xerosis bacillus**, in a case of spreading phlegmon, a sequence of chronic **otitis media**, and cholesteatoma; in a case of subacute, middle-ear disease; and in a case of **leptomeningitis**, secondary to ear disease. The bacillus was not found in the meningeal pus, but in the internal ear and in the facial canal. The organism was not pathogenic for animals. [D.R.]

3.—A **metapneumonic abscess** in the anterior abdominal wall, due to Fränkel's diplococcus. [D.R.]

4.—The patient, a man of 47 years, had taken a large quantity of apenta, with which **formalin** had in some way been mixed. The symptoms consisted of coma, lasting for several hours; anuria, persisting for 19 hours; redness of the conjunctiva and pharynx; and the presence of formic acid in the urine. The test for formalin in the urine consists in the development of a black color when the urine is heated with ammoniacal solution of silver nitrate. [D.R.]

5.—An instance of **hysterical fever**, with a review of the literature on the subject. [D.R.]

6.—Leutert, however, takes exception to Koerner's statement, and says that though everyone acknowledges the existence of the two forms of cholesteatoma, the true cholesteatoma is exceedingly rare, so much so that it is scarcely to be taken into our consideration as a factor of clinical importance. As regards the diagnosis of the presence of a cholesteatoma, this is not of vital importance, as the treatment in cases where there is suppuration of the **middle ear** is the same whether cholesteatoma is present or not. It is important, however, to locate the seat of disease, and this can be done with practical exactness by knowing the position of the perforation in the tympanic membrane. As to the treatment of these cases: In some of the middle-ear suppurations little can be done towards curing the condition, just as in cases of ozena of the nose. Other cases dependent on the presence of adenoids in the vault of the pharynx will not give way to treatment until the adenoids are removed. The chief indication is to remove the pus from the tympanum and surrounding cavities. This is done best by wiping away the discharge with a cotton applicator, or, better still, by blowing air through the eustachian catheter, or even syringing with a normal salt-solution through the catheter. Drainage through the external canal with strips of gauze has little to recommend it. Also the use of powder blown in through the canal is of little avail, except where the drum is almost entirely destroyed. When the perforation of the **drum membrane** is found situated in its upper part, indicating caries of the incus, operation, consisting of the removal of the two external ossicles, should be done. When there is indication of disease of the attic and of the ossicles, the removal of the latter furnishes the best means of draining the upper part of the tympanic cavity. Perforation in the posterior part of Shrapnell's membrane, running to the bony border, indicates disease of the antrum, and in these cases operation is always necessary. Stacke's operation generally affords the best results. [G.B.W.]

October 16, 1900. [47. Jahrg., No. 42.]

1. Cystitis Typhosa. CURSCHMANN.
2. A Contribution to the Knowledge of Lithopedons. KROEMER.
3. Disinfection with Smouldering Blocks of Carbolformal. DIEUDONNE.
4. The Frequency and Significance of Crystals in the Feces. SCHILLING.
5. The Cure of Hematuria, Due to Hemophilia by Gelatin. HAHN.
6. A Contribution to the Technic of Amputation Through the Leg. MENDEL.
7. The Earliest Stages of Idiopathic Cardiac Hypertrophy, and the Significance of Dilation as a Result of Weakness of the Cardiac Muscles, in Considering Availability for Military Service. WOLFFHÜGEL.

3.—Dieudonné has performed a series of experiments with the carbofomal smouldering blocks; these are really small rectangular blocks containing about 50 gm. of solid paraformaldehyd. When lighted, care should be taken that they do not burn with a flame, but simply glow slowly, so that the formaldehyd is liberated in the form of gas. It is exceedingly important in this method, that all the exposed surfaces should be thoroughly moistened with water.

To accomplish this, his method is to heat some stones red hot, and then pour boiling water over them; when steam is very rapidly produced. In the experiments the gas was allowed to act for about 7 hours, and it was found that a proportion of 6 blocks for each cubic meter of space in the room sufficed to kill all forms of bacteria, even the spores of anthrax. Smaller quantities, however, were inadequate. The method is particularly advantageous in the country, where elaborate apparatus for testing infection is not obtainable. [J.S.]

4.—Schilling has studied the **crystalline forms** that are found in the feces. The commonest are oxalates and carbonates of lime, and particularly the triple phosphates. The oxalates and the carbonates are found in the edible fungi. The triple phosphates occur in especially large numbers after indulgence in beef, pork, or game. They are present in stools with acid, as well as in those with alkaline reaction. The author mentions a number of other forms of diet giving rise to crystals, and describes certain chemical reactions by which their nature can be recognized. He admits that they are of little value in diagnosis. [J.S.]

5.—Hahn reports a case of **hematuria** due to hemophilia, in which, after other methods had failed to stop the hemorrhage, the patient was given large quantities of gelatin with his food. The result was excellent. He recommends the method on account of its simplicity and effectiveness. [J.S.]

7.—Wolffhügel concludes his paper upon the **idiopathic forms of cardiac hypertrophy**, and the significance of the forms of muscular weakness producing dilation, in deciding the question of military serviceableness. He believes that particularly among recruits there is a tendency to endeavor to perform their duties after symptoms of cardiac exhaustion are well pronounced. In other callings this is less likely to be the case, because a feeling of shame in admitting exhaustion is not so likely to be present. Moreover, the equipment of soldiers is so arranged that it diminishes the vital capacity of the lungs, and contributes in this way to the development of dyspnea. He calls attention to the distinction that should be made between mitral insufficiency which has a regulatory function, and that which is due to functional incapacity of the valves. In the latter, there is always dilation of the auricle, whereas in the former this does not occur. The regulatory form may be regarded as the resource possessed by the heart for escaping the results of pressure in the aorta, that cannot be overcome by the muscles of the left ventricle. Considerable valuable information is obtained by examination of the pulsation of the heart with the fluoroscope. He reports a very interesting case in which a man who had formerly been a locksmith, and had previously performed his military duties in an acceptable manner, after running a distance of about two miles and a half, suddenly fell dead. At the autopsy the right ventricle was enormously dilated, and there was also fatty degeneration in the heart wall. This patient had been in the habit of consuming large quantities of beer, but Wolffhügel believes that this was of less importance than the severe physical exertion to which he had been subjected for a long time. [J.S.]

Wiener klinische Wochenschrift.

October 4, 1900. [13. Jahrg., No. 40.]

1. Eulogy upon the late Professor Eduard Albert, with a Detailed list of all his Works Published. ADOLF LORENZ.
2. The Movements Seen in the Mouth and Throat, in Aortic Insufficiency. HERMANN SCHLESINGER.
3. The Treatment of Phthisis with Intravenous Injections of Hetol by Landerer's Method. ANTON KROKIEWICZ

2.—A **pulsation** has been noted in **aortic insufficiency** upon the mucous membrane of the mouth and pharynx, an inward movement, following the beat of the carotid, most marked in the tonsils and in the walls of the pharynx. Or a rhythmic swelling is seen passing in a wave over the softer parts, the tongue growing palpably thicker in systole, and decreasing during diastole, showing a difference of 1 to 1½ mm. When this phenomenon is well marked throughout the buccal mucous membrane, the cavity of the mouth grows periodically narrower. This pulsation in the tongue was noticed in 10 out of 40 cases. The tonsils, the palatine

arch, and uvula came next in frequency. The uniform narrowing of mouth and pharynx occurred 4 times in 40 cases. Once the right side of the uvula showed the pulsation, while the left side remained perfectly still. While not always seen, it is a **sign of great clinical interest**, and should always be sought. [M.O.]

3.—Krokiewicz treated 43 cases of phthisis with **injection of hetol**, increasing 0.0005 g. at each injection, repeated at intervals of 2 to 4 days, up to 0.005 g. In 25 cases this was the only treatment, the 18 others had subcutaneous injections of arsenious acid also. Recovery resulted in 1 case, 5 cases improved with the arsenic added, and 5 without, in all, **25% improved**. After a full review of the reports hitherto published, and a detailed list of his cases, he concludes that hetol injections are of use only in the very beginning of phthisis; that they cause a general leukocytosis, followed by local reaction and a tendency to heal, finally, and that they are not a specific against phthisis. [M.O.]

October 11, 1900. [13. Jahrg., No. 41.]

1. A Study of Trachoma. C. ZIEM.
2. The Normal Great-toe Reflex in Children. FRITZ PASSINI.
3. Formaldehyde Disinfection. BASIL KLUCZENKO.

1.—Will be abstracted in the next number.

2.—Passini confirms Babinski's observations that extension of the great toe follows tickling the sole of the foot in a patient with an organic lesion of the pyramidal tracts, while flexion occurs in normal individuals (**Babinski's reflex**). This extension is marked during the last day of tubercular meningitis, flexion generally occurring before that time. Extension occurs in very young children normally; only during the last three months of the first year does flexion appear. Well-developed infants may show it earlier, while backward children may give extension even after the first year. [M.O.]

3.—A 40% watery solution of formalin is the best for disinfection purposes. This is burned (the formaldehyde rising with the steam) for 7 hours, in a room, all the openings into which have been well closed. The articles to be disinfected therein should be spread out, so that the gas comes in contact with them. Before opening the room, **ammonia** should be introduced (a 25% watery solution being heated outside the door, the gas entering through the keyhole) which **unites with the formaldehyde gas, forming Hexamethylenetetramin**. An hour later, the windows should be opened wide, and the drops of steam which had condensed about the room carefully dried. No odor of the formaldehyde remains. [M.O.]

October 18, 1900. [13. Jahrg., No. 42.]

1. The Cortical Visual Centers. ST. BERNHEIMER.
2. A Peculiar Condition of Cyst Formation in the Central Nervous System, Postmortem. FRITZ HARTMANN.
3. A Study of Trachoma. C. ZIEM.

1.—After a complete review of the experiments done, and the conclusions reached by other investigators, Bernheimer describes his experiments upon the brains of embryos, infants, and children. His results confirm von Monakow's hypothesis, that there is no macula lutea center either in the anterior or the posterior part of the fovea calcarina. After detailed discussion of the views of the others, he concludes that light impulses will reach the cortex, perhaps somewhat weakened, even though the usual conducting fibers between the corpus geniculatum and the cortex are wholly or partially destroyed by disease, as the neighboring visual fibers, from their close contact in the internal capsule, can assume the function of the disabled bundles. Therefore, as long as any undiseased visual fibers exist, it is as hard to imagine the total abolition of the macula function as the existence of a circumscribed macula nucleus in the cortex. [M.O.]

2.—The patient, a major, aged 68, had a sudden attack of **unconsciousness**, followed by **aphasia**, **ptosis**, **right facial paralysis**, and drowsiness. Death occurred on the eighth day, total paraplegia having come on gradually. The autopsy revealed small cysts, containing gas in great quantities, and very sclerotic bloodvessels throughout the entire central nervous system. Small bacilli were found in the

bloodvessels of the brain and about the cysts. There were no signs of inflammatory or degenerative changes about the cysts. Hartmann believes that the bacilli entered through the circulation during life, but multiplied after death, and that the cysts were caused by the gas generated postmortem by the bacteria. The literature upon the subject is reviewed. [M.O.]

3.—Besides the theory of contagion from contact with gonorrheal patients, from towels, etc., generally accepted in our crowded communities as the cause of **trachoma**, Ziem gives the etiology of the disease in countries where it is epidemic or endemic (Hungary, Egypt, Syria, etc.). He divides the causes into (a) excessive heat and glare; (b) fine powder and dust; and (c) miasmatic material from swamps, moors, etc., which acts directly upon the conjunctiva or upon the mucous membrane of the nose; or, entering the alimentary tract, reaches the circulation, and finally becomes localized in the eye. In explanation of each, he gives long and interesting detailed, historical, and geographical facts, backed with references and statistics. Then he suggests numerous sanitary and hygienic measures tending to lessen the occurrence of this condition. [M.O.]

October 25, 1900. [13. Jahrg., No. 43.]

1. The Study of Hereditary Syphilis in the Second Generation. EDMOND FOURNIER.
2. The Occurrence of Acute Nephritis in Secondary Syphilis. (Nephritis Syphilitica Praecox). ABRAHAM STEPLER.
3. Echinococcus of the Kidney. LUDWIG STEIN.

1.—Fournier has collected the histories of the children born of the wedding of hereditary syphilites. Out of 45 such marriages, **abortion** occurred 43 times in 145 pregnancies, 39 infants were either still-born or died soon after birth, a total of 82 dead children (56%). Only 63 of these children lived, and they all showed some hereditary syphilitic stigmata. In 19 families, both grandparents were syphilitic, and one of the parents had hereditary syphilis. The histories of the 45 families are given. [M.O.]

2.—Stepler reports a case of **acute nephritis** occurring in a farmer, 20 years of age, 6 weeks after a chancre. In the urine were blood-corpuscles, casts, and 12% albumin. No other cause for the nephritis could be found, and mercurial inunctions, with potassium iodid internally, cured him in 7 weeks, by which time albumin and casts had disappeared. An extensive review of the literature of the subject follows, with a description of the cases of Dieulafoy and Etienne. [M.O.]

3.—Stein reports a case of **echinococcus cyst of the right kidney**, in which the surgeon removed the cyst, leaving drainage through the abdominal wound. The patient recovered in 24 days. After discussing the advisability of performing nephrectomy, in place of removing the tumor with subsequent drainage, he concludes that the decision must rest with the surgeon during operation, after he sees the exact condition present. [M.O.]

November 1, 1900. [13. Jahrg., No. 44.]

1. The Diagnosis of Latent Carcinoma of the Esophagus. C. HÖDLMOSE.
2. A Case of Posthemiplegic Intention Tremor. M. INFELD.
3. The Treatment of Epilepsy with Bromipin. WILHELM LORENZ.

1.—Hödlmoser reports two cases of **cancer of the esophagus**, in both of which the cardinal symptom, **dysphagia**, was absent. Unilateral recurrent paralysis was the one marked diagnostic symptom. The first case died with signs of a malignant neoplasm, localized within the gastrointestinal tract by epigastric pain, vomiting, and flatulence. There was great pain over the liver, which was hypertrophied and nodular; besides, a diffuse peritonitis. Chemical examination showed the absence of hydrochloric acid and lactic acid. The stomach was somewhat dilated. There were no esophageal symptoms; only the recurrent paralysis and some enlarged subclavicular lymph-glands. The second case, a woman who emaciated rapidly, complained of trouble in moving her tongue, with some pain in the neck. Her liver was hypertrophied, and both recurrent and hypoglossal nerves on the right side were paralyzed. The tumor was attached to a tubercular bronchial gland. [M.O.]

2.—Infeld describes in full a case of intention tremor in a man of 40, alcoholic, with a criminal history. When about 30 years old, signs of severe cranial disease appeared, unilateral headache, starting at a spot on the left side of the vertex, where he had been stabbed, and cerebral vomiting, followed suddenly by right-sided hemiplegia, with right-sided disturbances of vision and epileptic attacks (with biting of the tongue and involuntary micturition). These symptoms gradually grew better, leaving only paralysis of the right side. Two years later, the **intention tremor** appeared, at first in both right arm and leg, permanent, however, only in the hand. Right-sided ataxia also existed. The cause naturally seems to be some change in the brain, due to the injury, the alcohol, or both. The entire literature of the subject is given, with the quotation of many opinions, making a very interesting article. [M.O.]

3.—Lorenz used **bromipin** in 34 epileptic cases. In 11 patients the attack grew worse; in the rest they remained about the same. In 13 cases the number of attacks were less; in 3, the attacks were temporarily less frequent; the rest remained unchanged. The majority of the patients gained in weight, and seemed in better general condition. These results are far superior to those given by the opium-bromid treatment. [M.O.]

Berliner klinische Wochenschrift.

October 15, 1900. [37. Jahrg., No. 42.]

1. Hydrophobia up to the End of the Nineteenth Century. V. BABES.
2. Contributions Concerning the Action of Johimbine. A. LOEWY.
3. Downe's Urine Segregator. A. FREUDENBERG.
4. Several Cell Problems and Their Significance for the Scientific Establishment of Organotherapy. D. HANSE-MANN.
5. Methods for Preserving Anatomic Preparations True to Nature. L. PICK.

1.—Babes has concluded from a series of experiments that the changes in the **medulla oblongata** and **spinal cord** caused by hydrophobia are extensively diffused, in contradistinction to Schaffer, who believes that the changes are localized in those areas of the spinal cord into which those nerves enter that come from the wound. He states that it was not a sense of scientific investigation, but a pity for human suffering, which incited Pasteur's discovery. The results obtained in combating hydrophobia during the nineteenth century are from a practical point of view to be attributed to the preventative measures adopted by police departments and the enforcement of laws on sanitation. [M.R.D.]

4.—The author concludes his article by discussing the **biologic foundation** upon which organotherapy is based. There exists, according to the author's views, an altruistic relation between different varieties of cells and a **mutual sympathy** between a certain form of cell and the remaining variety. Changes in one form of cell are followed by changes in other varieties and in such a manner that a progressive metamorphosis leads to an altruistic **hypertrophy** while a regressive change leads to an altruistic **atrophy**. [M.R.D.]

4. Hemorrhagic Erosions of the Gastric Mucous Membrane. C. PARISER.
5. Hydrophobia up to the End of the Nineteenth Century. V. BABES.

1.—Tilmann, after reviewing the literature on the subject, reports 5 cases of his own. A thickening of some portions of the flexor tendons was found by him in each one of the

cases; the thickening was always found on those fingers which were employed in the performance of unusual manual labor, and which, according to the author, is the cause of the affection. The author's experiments upon the cadaver have shown that the localized thickening is due to the **bruising of the tendons** between the hard substance that is handled and the transverse ridges on the palmar aspect of the metacarpal bones. The treatment consists of immobilization of the finger by means of a splint, applications of tincture of iodine, and, later on, massage. In obstinate cases surgical intervention is the only means for procuring permanent relief. The author splits the tendon, removes the cicatricial nodule; this is generally followed by good results. [M.R.D.]

2.—Zili states that of the various theories advanced regarding the origin of eclampsia in pregnancy the one of Bouchard stands preeminently in the foreground. This author's explanation is that in eclampsia of the pregnant woman large quantities of **toxic materials accumulate in the organism** and cause the convulsions; the increased amount of metabolism caused by the fetus causes poisonous products to be thrown into the circulation. The liver is prevented from exerting antitoxic influence and the kidney is hindered in its process of elimination. These two points are especially emphasized by the French. The author obtains the degree of **molecular concentration** of the blood in eclampsia by comparing its **freezing point** with that of distilled water. He states that if the kidney is not able to eliminate the albuminous products of metabolism held in solution in the blood, the freezing point will be higher. The molecular concentration of normal blood-serum is constantly varying between 0.56–0.58° C. (Korányi, Dreser). It remains for the kidney by its properties of elimination to maintain this equilibrium. As small molecules like salts and the many derivatives of albumen metabolism slightly affect the freezing point, a special apparatus was employed. The blood was obtained partially by cups and partially by venesection, immediately after the convulsions. As Kovac has shown that carbon dioxide raises the freezing point, the blood was subjected to a stream of oxygen. After a series of experiments the following conclusions were deduced: (1) The blood in eclampsia does not show any appreciable variation in its freezing point from that of normal blood; (2) therefore in eclampsia there is no retention of urinary salts or of urea; (3) the normal value of the freezing point of the blood in eclampsia shows that the permeability of the kidneys is not affected in proportion to the most uremic processes; (4) we are therefore led to the assumption that the supposed toxic material responsible for eclampsia is to be found in a greater atom-complex than in a regressive albumen metabolism, probably an intermediate product derived from albumen molecules. [M.R.D.]

3.—Wohlgemuth states that a **fracture of the greater tuberosity of the humerus** occurs extremely rarely as an individual injury; it does occur, however, as an accompanying injury in luxation and fracture of the neck of the humerus. The rarity of the affection can be seen, when Gurlt could only collect 4 cases from literature. The diagnosis, although considerably assisted by the x-rays, can, nevertheless, be made sometimes from the clinical symptoms. These, however, are only characteristic when confined to the greater tuberosity. The symptoms are those which, in rare cases, are due to an extreme exertion of the supraspinatus, infraspinatus, and teres major muscles, like lifting with the outstretched arm, throwing missiles, and cracking a whip. The arm is slack, can only be raised with great pain, and the head of the bone can be plainly felt in the socket. But, at the first glance, the appearance of the shoulder is that of luxation, the deltoid being flattened, the acromion prominent, and the anteroposterior diameter of the shoulder is increased. On the other hand, the supra- and infra-spinatus muscles are not subject to tension, but are flabby, and upon careful palpation a small tumor will be felt next to the head of the bone, somewhat up and posterior; this is the fractured tuberosity, between which and the bone there extends a deep sulcus, in which is situated the tendon of the biceps. If pressure is made upon the tumor in the direction of the head of the humerus, and rotation at the same time performed, crepitus will almost always be felt, excepting in those cases where the tendon of the biceps has been interposed. External rotation of the arm is seriously impeded, because the points of insertion of the muscles have

been removed. If the fracture of the greater tuberosity, as is generally the case, is complicated by a subcoracoid or subglenoid luxation, the diagnosis is more difficult and almost impossible from the clinical manifestation, provided reduction has not yet been accomplished. There is considerable doubt as to whether luxation and fracture of the greater tuberosity occur simultaneously, and, if not, which one of the two affections is the primary one. [M.R.D.]

4.—Pariser gives a resumé of the views on this affection. The **symptoms** are anorexia, a burning pain in the gastric region, profound emaciation, and nausea; vomiting is rare. Unlike a gastric ulcer in which the character of the pain is cramp-like and nagging, in this affection it is of a markedly burning character. Examination of the gastric contents by means of the test-meal reveals little else in most of the cases than subacidity. The cause of the affection is a circulatory disturbance in the mucous membrane, causing acute inflammation and spasm of the muscular fibers. Observers differ as to whether this is a distinct affection *per se* or an indication of chronic gastritis. Treatment consists of gastric lavage with 1:1000 or 1:2000 solution of silver nitrate followed by neutralization with decinormal salt-solution. [M.R.D.]

October 29, 1900. [37. Jahrg., No. 44.]

1. Vesical Calculi. C. POSNER.
2. The Clinical Value of A. Schmidt's Method for Testing the Function of the Intestines. H. PHILIPPSOHN.
3. Rose's Diabetes Milk. SANDMEYER.
4. Four Cases of Disturbance of Equilibrium. RIEKEN.
5. Contribution to the Treatment of Callous, Resilient Strictures. H. LOHNSTEIN.

1.—Posner discusses at length the various theories regarding the etiology of **vesical calculi**. Palpation is of great value in recognizing the affection, especially in children. The addition of sounds, cystoscopy, and the x-ray render the diagnosis absolute. [M.R.D.]

3.—Sandmeyer states that Rose's diabetes milk, is absolutely **free from sugar**, contains but little albumin, considerable fat, and is of a pleasant taste. The author has employed it in about 50 cases of diabetes mellitus with excellent results. Even in very grave cases, he not only succeeded in maintaining the bodily weight, but often even increased it. Elaborate formulae are appended. [M.R.D.]

4.—In discussing this condition, Rieken believes it probable that **gastrointestinal autointoxication** is frequently responsible for this affection. He reports 4 cases which came on suddenly during damp weather, at a time when influenza and rheumatism were prevalent. The symptoms simulated in many respects Menière's symptom-complexes. The absence of deafness places these cases in sharp contradistinction to Menière's disease, and lead us to reflect whether there is not some unrecognized portion of the ear which, in its relation to the economy, may be the seat of these disturbances. [M.R.D.]

5.—Lohnstein has devised an instrument for the treatment of **callous, resilient strictures**. After dilatation and enlargement of the stricture ad maximum, the instrument, whose principle is that of a Bottini electric knife, is employed. The modification of the instrument is such that a urethrotome in a canula is formed. The author reports remarkable success in 17 cases. He considers the instrument as indicated in cases where there are cicatrices in the urethra that have run their full course. [M.R.D.]

4. Vesical Calculi. C. POSNER.
5. The Clinical Value of A. Schmidt's Method for Testing the Function of the Intestines. H. PHILIPPSOHN.

1.—Hitzig investigated the relation of the **reflex closing of the lids** to the visual disturbances produced in dogs by operating on certain areas of the occipital lobe. He found that the disturbance of the optic reflex was entirely independent from the visual disturbances. Injuries to the motor areas of the cortex also, as a rule, disturb the motor func-

tions connected with the act of vision, that is, the optic lid reflex, while in disturbances of the sensory portion of the cortex this may not occur. According to the author, the disturbance of the optic reflex can only be due to a lesion of the **subcortical center**. [M.R.D.]

2.—Thumin reports a case of repeated renal colic, on the right side, in a woman aged 31. Repeated examinations of the ureter by means of a catheter gave negative results. Later on, however, a diagnosis of **purulent pyelitis** of the right kidney was made. In order to test the functional activity of the right kidney, the phloridzin test was employed. The left kidney was found to be secreting normally and the right not, showing a disease of the parenchyma. Complete recovery after nephrectomy, and confirmation of the diagnosis upon examining the pathologic anatomy of the diseased viscus. [M.R.D.]

3.—The author makes a plea not to neglect the tonsils in all cases and varieties of rheumatism. He refers to the extensive literature on the subject concerning the relation between **tonsillitis** and **rheumatism**. He quotes 4 cases occurring in his own practice in which tonsillitis was followed by a typical petechial rash resembling purpura. It is not necessary that the throat symptoms should be of a very severe nature, but that sometimes they may be very mild and yet the constitutional symptoms of rheumatism be quite severe. [M.R.D.]

2. Autopsy in a Case of Akromegaly. E. MENDEL.
3. The Treatment of Catarrhal Adhesive Processes in the Middle Ear by Intratubular Pilocarpin Injections. F. FISCHENICH.
4. The Clinical Value of A. Schmidt's Method for Testing the Function of the Intestines. H. PHILIPPSOHN.

1.—Bernhardt has observed in cases of congenital and early acquired facial paralysis that the musculature of the paralyzed side contracted when the facial nerve of the **unaffected** side was subjected to electric stimulation, and that this even occurred when currents were employed which would not even affect the healthy side. He believes this to be due to the **anatomic relations** that exist between the facial musculature of the right and left sides. The fact that in healthy individuals electric irritation of one side will not bring about contractions of the opposite one is not considered to be of value in pathologic conditions. [M.R.D.]

2.—Postmortem examination of a case of **akromegaly** occurring in a woman of 25, that had been under observation for some time, is reported by Mendel. Upon opening the cranium the external surface of the dura was found to be markedly adherent. The inner surface of the dura was smooth, and the sinuses were bloodless. At the base of the brain, near the chiasma, a sarcoma a little larger than a walnut, and composed of large, round cells, was found. The pineal gland was throughout normal. The thyroid gland was considerably enlarged, and extended to the lower border of the manubrium. In the anterior mediastinum there was found a vestige of the thymus gland about 8 cm. in length. The spleen was very soft; the right ovary was the seat of cystic degeneration; the left ovary normal. The breasts were markedly developed. Heart, lungs, liver, and kidneys were normal. The bones of the skeleton, excepting the symmetrical increase in volume, were normal. There were nowhere any osteophytic deposits. [M.R.D.]

3.—Fischenich recommends the employment of a 2% aqueous solution of **pilocarpin muriate** as an injection, for catarrhal adhesive processes in the middle ear. The dose varies from 6 to 16 drops, and is often followed by dizziness, which only lasts for a brief period. The acoustic acuity may even increase after treatment has been stopped. The injections are made with a catheter in the usual manner, and may have to be repeated 30 to 50 times. [M.R.D.]

5. The Skiagram of a Metal Spoon in the Esophagus of an Adult Maniac.

1.—Hellendall describes a procedure which is not widely different from that of Abbé [see *Münch. med. Wochenschrift* abstract] excepting that the latter author put a band around the body while he describes an **apparatus** which consists of suspenders thrown over the shoulder to keep the apparatus in the proper vertical position, and a band passing around the body holding a spring and pad, so that the result is much like that of a truss, the pressure being exerted almost exclusively on the pad and there being no compression of the chest in general. The pad is placed below the left breast so as to give support to the heart. He states that the results from the use of this apparatus have seemed to him excellent, and he believes they cannot be explained through suggestion alone. He found that the apparatus was not usually of practical value except in the after-treatment in organic cases, but it was then worn with great satisfaction. In purely functional cases it may be worn with great comfort through the course of the treatment. Unfavorable effects were not observed, and the patients all stated that they felt a general sense of comfort. The palpitation became less, there was less dyspnea, and the patients were all unwilling to stop the use of the apparatus after they had once tried it. [D.L.E.]

2.—The article is a reply to a recent article of Beck and Rabinowitch, abstracted in this journal from the same source. As to the criticisms of the German authors concerning the **bacillus** used by Arloing and Courmont, the latter authors state that it comes from the ordinary **bacillus** of Koch, and always retains the fundamental peculiarity that it produces tubercles, but under different circumstances from the ordinary bacillus. As to the criticism that no such agglutination and clarification of the fluid could be observed as in cholera and typhoid, they state that the phenomenon of agglutination is one that is subject to a certain amount of variation with whatever variety of bacillus it is undertaken, depending upon the energy of the action taking place between the agglutinating and agglutinated substances. They consider that more or less variation in the behavior in tuberculosis as compared with that in typhoid cannot stamp the test at once as valueless. The most stinging part of their communication is their study of the tables presented by Beck and Rabinowitch, and the substance of the final statements of Arloing and Courmont is that a careful observation of the tables reported by the German authors will show that while they state that they compared in 73 cases the reaction to tuberculin with the serum reaction, one can readily see that the tuberculin reaction was either carried out only 11 times, or that it was negative in all but 10 cases. The only conclusion to be reached is that the serum-reaction was really not compared with the tuberculin-reaction, or that the tuberculin-reaction was positive in only 10 of the tuberculous subjects. In the latter case Arloing and Courmont state that they are content to rest upon the testimony offered since it shows that the serum-reaction was positive in a larger number of cases than the tuberculin reaction. They also report their results from the serum-diagnosis of 80 calves and 70 cows, the latter of which were more or less tuberculous. Autopsies were made by public inspectors who knew nothing of the result of serum-diagnosis. The calves were all free from tuberculosis, and none of them gave reaction in a dilution as high as 1:5. With one exception all the tuberculous cattle gave a reaction in a dilution greater than 1:10. They state that they do not consider that the serum reaction can be absolutely depended upon in every case, but it is very easily carried out when the proper cultures are obtained; it does not in any way interfere with the comfort of the patient, and it could be undertaken in every case without objection from the patient. [D.L.E.]

3.—Ziemann continues his article by considering the treatment. **Quinin** is a sovereign remedy. **Phenocoll** and **methylene-blue** he found practically useless. Quinin should be given during the intermission, and not during the fever; 30 grains a day is the largest dose necessary. He

believes that quinin acts directly upon the protoplasm and the parasites, and only secondarily upon the chromatin. If patients are very sensitive to quinin, he considers euechinin very useful. He has found quinin a very valuable prophylactic; the amount, then, given should depend upon the individual and upon the region in which he lives. He believes, however, that it should be given every 4 days, in doses of about 7 grains, on an empty stomach. This will not absolutely secure one from an attack of malaria; but if malaria does occur, it is milder and is much more readily managed by treatment. The proper hygienic conditions of the dwellings, proper clothing and food, are extremely important in prophylaxis. Soldiers sent to the tropics should be at least 25 years old, and should be well-chosen, thoroughly healthy men. Ziemann was able, in Kamerun, Victoria, and also in Togo, to find specimens of the *Anopheles* containing malarial parasites. He considers this testimony that the mosquito is probably very active in these regions in spreading the disease. The methods in attempting to stamp out malaria which he recommends are: To keep well covered at night with mosquito nets; keep rooms well aired and lighted, so that the mosquitos will not collect in them; turn the sea-water into fresh ponds along the coast, where possible; and use petroleum upon the surface of stagnant water, when this can be carried out. The latter procedure, in Ziemann's belief, can very inexpensively and readily be made of a good deal of value in many regions. He insists, also, that the blacks, whose hygiene is never good, should not be allowed to collect in the neighborhood of whites. Quinin prophylaxis, as recommended by Koch, he is inclined to think, is an idle dream, as it can be done only in individuals, and in order to be effectual it should be carried out in every person in the neighborhood who had malaria or who is likely to have a relapse of old malaria. This Ziemann considers impossible, but he does believe that quinin can be made very useful in prophylaxis in a good many individual cases, and particularly among the whites. He is rather inclined to believe that man is the only intermediate host of the malaria parasite. [D.L.E.]

4.—Schönberg does not believe it possible for physicians in private practice to become expert enough in the use of the x-rays to make a careful diagnosis on account of the technical knowledge required. Improvements are constantly being made in the apparatus and a person not familiar with the technic is unable to decide the usefulness. The quality of the ray depends upon the management, and kind of apparatus used, the light should be steady and especially so for the instantaneous work and for this a good current breaker is required. Some of the mechanical breakers, those with a stream of mercury, are very good, and the Wehnelt is a good one also, but it makes too much noise and the fumes of sulfuric acid cause considerable inconvenience. For tissue differentiation a lamp with a good vacuum regulator is needed and for carrying large currents some cooling device is necessary, and it is with these tubes that pictures of sclerosed arteries, thickened joints, etc., can be made as well as examinations of the chest for pathologic processes in the heart and lungs. [W.S.N.]

5.—Stembo found by means of the x-rays a spoon in the esophagus in a man suffering from melancholia, the bowl of the spoon was toward the stomach, the length 20½ cm., width 4.1 cm. It was removed by performing a gastrostomy. [W.S.N.]

1.—Koch's article is a general review of the observations made in his foreign expedition. In German East Africa he found beside the ordinary tertian and quartan parasites only

one parasite which is of ring form or half-moon shape, and produces fever attacks of a distinctly tertian type, the type becoming irregular if quinin has been used. This type of fever he prefers to call tropical fever, and the parasite the tropical parasite. He found that an enormous percentage of the children in various regions showed evidences of malaria, while as age advanced the percentage of those affected decreased very decidedly. He considers from this that there is evidence of the existence of an acquired immunity in a very large percentage of the natives. He believes that this immunity is further shown by the fact that many of the adults, if they go from one region to another where malaria is rife, are not attacked by the disease. He does not think that the reason that so many children are affected is because they are excessively susceptible rather than that adults are partially immune; were that the case he thinks they would become constantly more gravely ill, and finally would all die. The susceptibility that exists in adults is often sufficient to cause their death, and if the figures in children were due merely to a greater native susceptibility the mortality among them would be extremely great. His method of examining for parasites is as follows: After making smears, the preparations are moved rapidly to and fro until they are dry, often a difficult thing to accomplish, since in the tropics the humidity is sometimes 100%; they are then placed in a box surrounded by blotting paper and put in a glass receptacle which is well stoppered, and which contains a little calcium chlorid. This prevents the preparations from spoiling as a result of the constant humidity. He fixes by holding the preparation in the fingers over a flame and warming, then putting them in absolute alcohol. He stains with borax methylene-blue obtained from the Hoechst factory. Examinations of the spleen in children discovered this organ often extremely large. This is found only rarely in very young infants. It was found once in a child 6 months old, and never below this age. It is most common between 3 and 6 years of age. Splenic tumor and malaria vanish spontaneously later on, and in later life there are no evidences of malaria left, and the children become strong and healthy adults. He thinks that malarial cachexia occurs only in those who have not acquired a sufficient degree of immunity. [D.L.E.]

2.—Ziegler gives a general review of the question. Scar tissue is usually fibrous connective tissue. In the skeleton it often changes into cartilage, then into bony tissue, and finally into well-formed bone containing marrow. The scars of the skin, intestine, genital organs, lungs, spleen, lymph-glands, heart, bloodvessels, brain, and various glands, are generally connective tissue scars which may be covered by epithelium. In the liver it is not uncommon to find the production of new bile channels, and in the intestinal and uterine mucous membranes the scars are frequently covered by epithelium, and this may grow into the scar and assume the character of glands. In the kidneys and testicles, while damaged tubules may acquire new epithelium, there is no real production of new tubules. In the brain and spinal cord there may be, besides the connective tissue production, some growth of glia, but this is of relatively slight importance. The muscles may produce new muscle fibers, after a time largely replacing the scars. This does not occur to any extent in the unstriated muscular tissue. Peripheral nerves heal by the production of new connective tissue, and there is also a considerable production of new nerves, so that the scars are traversed by numerous new nerves. There may be a new production of glandular cells in the liver, the kidneys, the mucous glands, the thyroid, and in the genital glands. Those cells which show the most ready new growth are the cells of the fibrillar and areolar connective tissue and the endothelium of the blood and lymph vessels. Cartilaginous tissues show new growth only imperfectly. Nerve-fibers grow purely through outgrowths from the axis-cylinder. In some cases when the tissues of the damaged area are unable to cover in the defect, transplantation of tissue of the same kind from elsewhere will accomplish the desired result. All animal organisms have the power to replace in some way tissue that has been lost; a number of instances are mentioned, including protozoa and higher forms of life. When tissues which are not replaceable by local growth are lost, and thus cause damage to the organism, there is a compensatory growth of the remaining tissues and an increased function of these tissues. The cause of the repair of the tissues after injury lies in the power of growth and proliferation that the

tissues show. The starting point in this growth is in the fact that some of the factors which hinder growth are done away with by the injury. In compensatory hypertrophy of the tissues the cause of the new growth is to be found in the increase of function which acts both as a nutritive and formative irritant. [D.L.E.]

3.—The case reported was that of a child of 10. There was severe diphtheria of the throat and subsequently a widespread involvement of various nerves with marked paralysis and ataxia of the lower extremities. There was also some paralysis of the hypoglossus and of the left side of the soft palate and of the left vocal cord. Ocular accommodation was largely paralyzed, and there was much decrease of sensation in the legs. These nervous changes improved slowly. While in the hospital the child had sudden and violent attacks of apnea. In the first attack it looked as if the upper respiratory passages had been plugged by mucus, and the child seemed about to die. Removal of the mucus from the mouth and throat did no good; on the contrary, the apnea increased and persisted for 4 hours, and the child was kept alive only by artificial respiration. These attacks were repeated five times. They varied in duration from 5 to 34 hours. There was after the first attacks evidently some aspiration pneumonia, but the attacks in general were certainly not due to any local change in the lungs. There was no paralysis of the diaphragm. The only cause to be thought of was either a lesion of the respiratory center or of the nerves coming therefrom. The most satisfactory explanation is, in Ebstein's belief, a lesion in the respiratory center produced by a poison, probably produced by the diphtheria directly. [D.L.E.]

4.—Quincke reports the case of a child who had the following history: It was born in 1896 of tuberculous parents. It had had some skin eruption when six weeks old, but no other definite signs. When about six months old the child was brought to the clinic because it swallowed badly. The tongue was thick, the child was lethargic, did not know the mother, had a coarse voice, had a cretin-like face, the nose was broad, the body was moderately nourished. The thyroid gland was found to be a small hard tumor about the size of a pea. The child was given iodothyron with some improvement. Afterward thyraden was added, and the child improved very greatly. When the thyraden was stopped the child grew worse again, and when the thyraden was once more ordered there was again a very marked improvement. The child had distinctly improved, when three years after first seen it disappeared from observation. Even at that time, however, the improvement had been only moderate. The child died in 1900 of an intestinal affection. The postmortem showed brownish stumps of teeth, the fontanel was only imperfectly ossified, the thymus was found very small, and the thyroid gland was absent. The adrenals were not discoverable. Quincke directs attention to the fact that there was evidently a progressive atrophy of the thyroid gland in this case, so that it was entirely gone when the child died, in its fourth year. In other words, that the change was a progressive pathological process in the gland, and not congenital absence of the gland. The cretin-like symptoms appeared in the first six months of life. It was notable that the skin was not like that of myxedema, but soft, though somewhat thickened. Unusual symptoms were nystagmus, a shaking movement of the head, and it was notable that the child's height was not below the normal. The case is additional proof of Kocher's view that cretinism is due to a qualitative or quantitative change in the thyroid function. It is possible that special toxins are active in the disease, and that they damage both the thyroid gland and other organs, so that the picture of the disease is due not only to damage of the thyroid gland, but to the effect upon other organs. [D.L.E.]

5.—There has been, in Neisser's belief, sufficient testimony in many ways to show that there are numerous anti-bodies in normal serum. An example which proves this is the fact, which has been demonstrated, that horse-serum will protect rabbit's blood-corpuscles against tetanolyisin or staphylo-lysin, and other hemolysins, and that there is apparently a distinctly qualitative difference in the action of the horse-serum toward these various hemolysins. When anti-hemolysins are used, it is found that they act only against the homologous hemolysins. Further demonstration of the multiplicity of the anti-bodies is shown by the work which Neisser reports here. He took the serum from 4 normal horses,

and determined quantitatively their anti-action upon tetanolyisin and staphylo-lysin; he then determined the amount of staphylo-lysin and tetanolyisin which produced complete solution of the corpuscles in one drop of rabbit's blood, and then determined the amount of horse-serum which sufficed to overcome completely the dissolving influence of these poisons. The result was that the influence of the four serums upon the tetanolyisin and the staphylo-lysin was very different. The ratio of action upon the tetanolyisin and the action upon the staphylo-lysin in the first serum was 1:10, in the second serum 1:0.67, in the third 1: over 40, in the fourth 1:1. Such results can be explained only by the acceptance of two different anti-bodies. [D.L.E.]

6.—A description of a special thermoregulator for use in cases in which skin diseases, severe burns, etc., require prolonged and permanent baths.

7.—Methyltrolycarbinolurethan has been given in oblate form and has no unpleasant taste. The dose used is from 7 grains to 30 grains. The use to which it was put was to produce sleep in simple insomnia produced by overexcitement, hysteria, neurasthenia, old age, etc. Seventy-two cases are reported. The conclusion reached was that it can be well given in any case in which sleeplessness is not produced by pain. Sleep is usually induced within an hour. No unpleasant collateral effects of any kind were observed. One advantage over other hypnotics is that one can increase to relatively high doses if necessary. [D.L.E.]

8.—Auerbach and Unger made cultures from the blood of 10 cases of typhoid fever, obtaining the blood by introducing a needle into a vein. In 7 of these cases bacilli were obtained. Only 1 of these was a severe and fatal case. The others were mild or only moderately severe. The tests were made between the twelfth and forty-second days. The cultures were made in about 300 cc. of bouillon in an Ehrlenmeyer's flask; 18 to 24 hours afterward hanging drops were prepared, and usually the bacilli were at once visible. They were afterwards identified by the usual means. The authors consider that this procedure is a very valuable diagnostic measure. It is but little more difficult to carry out than the Widal test, or bacteriological examination of the spots. In one case in which the Widal test was negative the spots were absent, but the diazo reaction was positive. Cultures showed the presence of typhoid bacilli in the blood. [D.L.E.]

Neurologisches Centralblatt.

December 15, 1900. [19. Jahrg., No. 24.]

1. The Venereal Paralysis of Horses; a Contribution to Comparative Neuropathology. J. MAREK.
2. The Technic of Nerve-cell Staining. M. BIELSCHOWSKI and M. PLIEN.

1.—Marek has made some very interesting studies upon a venereal disease that apparently occurs only in horses, and is characterized by a slight local catarrh with the formation of small nodules and erosions. At rather variable intervals there appear spots on the skin about the size of a thaler, and slightly elevated. They are not tender nor warm. These disappear in the course of from 1 to 8 days, others reappearing in different parts. The animals suffer from a general pruritis and hyperesthesia of the skin. The nerve-trunks are tender, the cutaneous reflexes are exaggerated, the tendon reflexes are lost or diminished. The electric reactions of the parietic muscles are very greatly decreased, or show the characteristics of degeneration. The animals show various degrees of paralysis, and may die of sloughing sores. Microscopically the brain and spinal cord are normal, the peripheral nerves show the characteristic changes of neuritis; there is round-cell infiltration, particularly in the neighborhood of the bloodvessels, and degeneration and disappearance of the nerve-fibers. In the muscles there is some degeneration of the intramuscular nerve-fibers, but no inflammatory change. Marek regards the condition as a type of polyneuritis infectiosa equorum.

2.—Bielchowski and Plien recommend very highly the use of cresylviolet for staining nerve tissues. It has a strong affinity for the chromophilic substance, and appears to replace thionin, toluidin-blue and methylene-blue, and it gives a metachromatic effect with basophilic granules and amyloid substance. [J.S.]

Original Articles.

TWO CASES OF EPILOPEXY IN CIRRHOSIS OF THE LIVER.*

By JOHN B. ROBERTS, M.D.,

of Philadelphia.

THE suggestion to suture the great omentum to the anterior abdominal wall for the purpose of establishing a collateral venous circulation, in cases of cirrhosis of the liver, appears to be founded on good physiological premises. Two cases recently operated upon are, perhaps, worthy of record.

The previous history of Case No. 1 is as follows:

A man, aged 49, of temperate habits, whose father it is said died of cirrhosis of the liver, though he also was a temperate man, came under my care for distention of the abdomen in November, 1900. He was referred to me on account of the cause of the abdominal distention and the ascites being obscure. The slight yellow tinge of his conjunctivae and the other symptoms led me to believe that the abdominal dropsy was due to cirrhosis of the liver. One of the other physicians who saw him was inclined to the diagnosis of tubercular peritonitis. The distention of the abdomen began about 3 months before I saw him. There had been some jaundice varying in degree for about 2 months.

It was determined to evacuate the fluid in the peritoneal cavity, and at the same time explore the condition of the abdominal organs, by an incision, which would permit the entrance of my finger. A 3-inch incision was made in the middle line above the umbilicus. This disclosed a hardened liver with a roughened surface, and the diagnosis of hepatic cirrhosis was made. This operation was done under ether narcosis, because the patient complained so much of the manipulations, after the abdominal incision had been made under local anesthesia with cocain. The wound was closed with interrupted sutures.

The patient for a number of days suffered from partial suppression of the urine, due evidently to the ether and the cirrhotic condition of the kidneys. An examination of the urine had shown albuminuria and casts. Under the use of pilocarpin his condition improved, and 24 days after the first operation omental fixation was performed.

On December 4, 1900, the patient was operated upon under local anesthesia with cocain. He was given, about half an hour previous to operation, a hypodermic injection of a quarter of a grain of morphin and a hundredth of a grain of atropin. The tissues in the middle line above the umbilicus were then infiltrated with Schleich's solution No. 2. The incision was made in the line of the previous exploration wound. A 2-inch incision was sufficient to admit the forefinger of the operator and permit the necessary intraabdominal manipulations. Inspection of the omentum showed near its lower margin a small white nodule of hard consistence. This was about the size of a pea; and, with a portion of the omentum, was excised in order to permit subsequent microscopic examination. It was thought possible that it might be malignant in character, though the exploration of the surface of the liver with the finger, made at the time of the previous operation, revealed no nodules in the liver as far as its surface could be examined through the small wound.

The peritoneal surface on each side of the abdominal wound was rubbed with a finger, covered with a layer of gauze, for the purpose of irritating its serous surface. The omentum was then spread out and stitched on each side of the wound by four sutures of chromicized catgut. These were introduced from the cutaneous surface through the entire thickness of the abdominal wall. For this purpose a large curved needle was used. The chromicized catgut employed for suturing purposes was tied on the external surface of the belly. The amount of skin included in each stitch was about one inch. The abdominal wound was then closed

with interrupted catgut-sutures and the whole surface covered with gauze and collodion. The two outer fixation-sutures ran horizontally across the abdomen; the two near the middle line lay a little obliquely upwards and inwards. The two-inch incision gave sufficient room for manipulation and seemed to be more desirable than a longer incision, which would have been required, if the sutures had been introduced through the omentum and the internal tissues of the abdominal wall, from within the abdominal cavity. The long sutures carried through the skin would, it was thought, give a broader surface of contact between the omentum and the peritoneum than the shorter sutures usually used when intraabdominal suturing is employed. A month later the patient had less ascites and the external veins of the abdomen and anterior surface of the chest seemed much more distended than before. His general condition was that of advanced liver and kidney disease. He was more jaundiced and more drowsy. He died about 6 weeks after the epiploxy. An examination by Dr. Stahr showed the omentum attached to the belly-wall for about 3 inches. The nodule taken from the omentum resembled a spindle-cell sarcoma. A full autopsy was not made.

The other case operated upon on the same day had a previous history as follows:

A man, aged 54, stated that he had been a heavy drinker and that for the last 8 months the abdomen had become distended. Since the abdominal swelling had first been noticed by him, he had been tapped eight times. It was probable that the disease had existed much longer than 8 months. When I first saw the patient he was emaciated, a good deal jaundiced and very weak. His nervous condition suggested the possibility of approaching delirium tremens. The abdomen was greatly distended with fluid and the superficial veins of the abdomen were very prominent. There was edema of both legs. Examination of the urine showed albumin and a few hyalin casts to be present.

The man's general condition was so bad that instead of suturing the omentum to the abdominal wall, as I was inclined to do, I simply tapped him and drew off 6 pints of ascitic fluid. This was on November 26, 1900. Eight days later, operation for evacuation of the fluid in the abdomen and epiploxy was done. At that time there was scanty urine, and the man was still in bad condition, though better than when I first saw him.

In this instance a 2 inch incision was made in the middle line, just below the umbilicus, because I thought that I could probably reach the lower portion of the omentum better than if the incision was made above the umbilicus. I found, however, that it was impossible to reach the omentum with my finger, because it had been pushed upwards by the intestines floating upon the ascitic fluid. Even when the fluid, which was large in amount, was emptied from the abdomen through the opening, the omentum could not be felt. A second incision of about the same length was therefore made above the umbilicus. The omentum was then found and pushed downward, so that it could be reached with the finger introduced through the lower incision. It was then very easy to spread out the omental tissues; and two sutures of chromicized catgut were introduced on each side of the upper incision. While the sutures were introduced, the forefinger of the operator's right hand was introduced through the lower opening to hold the omentum in place and protect the intestines from injury with the needle, which was carried through the entire thickness of the belly-wall with the left hand. This operation, which was done under cocain anesthesia, was made quite easy because of the great relaxation of the anterior belly-wall, due to the prolonged dropsy of the peritoneum. The assistant was able to pick up the relaxed wall in a vertical fold so that the curved needle could be introduced without going near the intestine. This was probably an error in technic, as it made the sutures more liable to tear through the omentum when the abdominal wall was released by the fingers.

The patient died in uremic coma the day after the operation. On opening the abdomen three of the stitches were found to have torn through the omentum. At the place of one stitch a small portion of the omentum was still held against the abdominal wall, and in

* Read before the Philadelphia County Medical Society, January 23, 1901.

two places an ecchymosis was seen in the tissue of the omentum showing where the needle puncture had been made at the time it was sutured to the belly-wall. One stitch was still holding. There was no evidence of inflammatory lymph at the point where the stitches were inserted. This probably was due to the weak condition of the patient at the time of the operation. The liver was very small and hard and the surface nodular. It was in appearance a typical hobnail liver. The kidneys were small, with notched surface and adherent capsule. The cortex was diminished in amount. Microscopic examination subsequently showed the cirrhotic nature of the hepatic condition.

It is much too early to reach a definite conclusion as to the clinical value of epiploexy in cirrhotic liver; but the operation is so comparatively trivial and the disease so intractable that a comparatively early resort to it seems justifiable. Both of these cases would have been operated upon earlier by me, if the general condition had been better.

The patient whose operation is reported first became seriously ill from partial suppression of urine after the exploratory operation done to determine whether he was suffering from tubercular peritonitis or cirrhosis of the liver. That operation had been started under anesthesia by cocain, but was concluded under ether because of the patient's assertion that he was being hurt. It was this serious condition, the result of etherization in connection with his bad kidneys and liver, that made me a little anxious about the operation for fixing the omentum.

The case which is here reported as No. 2 was exceedingly ill when first brought under my observation, with edema of the lungs and a nervousness which seemed to indicate the probable occurrence of delirium tremens. He was in a bad condition when operated upon, having passed for a few days previously a much less amount of urine daily than is physiological. I was led, however, to operate upon both cases because of their apparent hopelessness under medicinal treatment.

These cases have taught me a few points in regard to the technic of the operation. I believe the method carried out in them is, in general, the best. By this I mean that the incision should be made above the umbilicus under local anesthesia, and that the sutures should be carried through the external skin by means of a curved needle, while the forefinger of one hand within the abdomen holds the omentum against the anterior abdominal wall. It probably is unimportant whether or not the parietal peritoneum be previously scraped with a curet or rubbed with a finger covered with gauze. It is, however, important that the omentum be rolled up a little, at the point of each suture, into a sort of cord, so as to prevent the stitch tearing through the friable tissue. The stitch should include quite a wide area of omental structure. On this account it is undesirable that the anterior abdominal be pinched into a fold during the insertion of a stitch, because when the tissues are relaxed the catgut-suture is liable to tear through the omentum.

I had originally intended in these cases to make a sort of rope of part of the omentum and stitch this in the incision in the anterior wall, so that the omental tissue would be in contact with the superficial fascia. I had thought of even spreading its end out under the skin. I did not do this because I thought the contraction of the scar-tissue in the wound would prevent venous circulation through the portion of omentum thus drawn

through of the muscular wall. The importance of keeping the omentum fixed against the peritoneal surface of the wall of the abdomen until adhesion occurs, makes it desirable that it should be thus caught in the wound. Even if cicatricial contraction prevents circulation through the scar, and even if a weak spot is made in the wall, creating a liability to hernia, I believe that such fixation in the wound is important.

I did not undertake to stitch the surface of the liver to the anterior wall of the abdomen in either case. In both instances the disease was so marked that it would probably have been difficult to have pushed the small liver forward against the abdominal wall and to have held it there by suturing, without causing greater tension on the sutures than is desirable. Epiploexy, should, in my opinion, be done as soon as practicable after the diagnosis of cirrhosis of the liver is made. In late cases the operation will probably not be of much therapeutic service. It seems as if there were good physiological grounds for believing it advantageous in early cases. The discomfort liable to arise from the abnormal adhesions and the remote possibility of intestinal obstruction by entanglement of the small bowel are too unimportant to weigh against the possibility of delaying the onward march of an almost hopeless, progressive, hepatic disease.

THE SURGERY OF THE STOMACH.*

By ALBERT L. BOUFFLEUR, M.D.

of Chicago

BEFORE considering the subject assigned to me, I desire to express to the officers and members of the Society my keen appreciation of the honor conferred upon me in my selection as one of the speakers upon this memorable occasion.

It was, however, with considerable diffidence that I consented to present such a large and important subject in the limits of a single paper before such a critical audience; knowing as I did, that it would be impossible to do the subject full justice in so short a time, and that to cover it at all would mean the briefest mention of several conditions and procedures, any of which might claim our attention for a whole hour, and feeling as I did, that there are members of your Association who are able to speak authoritatively upon the matters to be considered.

The phase of the symposium upon which I have been requested to address you forms one of the most interesting chapters in modern surgery. While gastrotomy was performed as early as 1602 by Mathis and again in 1635 by Schwabe, the works on surgery gave it but little attention until quite recently; and likewise, Sedillot seems to have performed gastrotomy as early as 1849, but the operation was practically unheard of until 1886 when Hacker again presented the subject.

Modern gastric surgery can be said to have begun about 25 years ago, when Billroth and his assistants began to develop the technic which has made the subsequent wonderful procedures possible. The radical measures seem to have preceded the milder ones in the surgery of this organ. Billroth successfully performed pylorotomy in 1891, while Heinecke and Mikulicz presented pyloroplasty in 1886-7. The great mortality of

* Address delivered before the Michigan State Medical Society, Mackinac Island, Mich., July, 1900.

the more radical procedures, even in the hands of such experts, made the necessity of less heroic measures imperative. This is frequently the case in surgery; the ideal giving way to the practicable.

With the wonderful strides of abdominal surgery, that of the stomach kept pace, and within a brief space of 10 years nearly all of our present procedures were successfully performed. Since 1890 the progress has been in the direction of modifying and improving the technic of the established procedures, and in widening the scope of their application until, as a fitting climax to the close of the brilliant nineteenth century, the most formidable of all possible operations upon the stomach—its total extirpation—was successfully performed.

The stomach forms such an important part of the *primæ viæ* that its presence has until comparatively recently seemed absolutely indispensable to life. While from practical experience it has been known for years that a patient could not only be sustained but hypernourished per rectum, and while resections of the major portion of the stomach had been successfully performed several times, it remained for Schlatter, a bold Swiss surgeon, to positively demonstrate that man could not only withstand the operation of total gastrectomy, but that the functions of assimilation and general bodily nutrition could be carried on quite satisfactorily without any stomach.

While this fact, perhaps, is of the greatest interest to the physiologist, it serves its purpose for the surgeon by demonstrating conclusively that it is admissible for us to resect larger areas of the stomach and even the whole of that organ for local disease and thereby to give to our patients greater chances of freedom from local recurrence.

The surgery of the stomach has been made possible by the fact that rectal feeding is feasible and practicable in all cases, at least for a few days. While operative measures were formerly largely for emergency conditions, the absence of the necessity for nourishment by mouth, the frequency with which early diagnosis is now made, the greater simplicity and perfection of operative technic and the increased dexterity of operators have made it practicable to operate for elective as well as emergency conditions.

The surgery of the stomach can very properly be divided into operations for disease of the stomach itself and for conditions incident to the disease of other organs.

Diseases or conditions of the stomach which may require operative treatment are congenital and acquired deformities, wounds, stenosis or orifices, dilation, displacement, ulcer and cancer. The presence of foreign bodies in the stomach also call for surgical measures. The two conditions of other organs most likely to call for operation upon the stomach is stricture—malignant or benign—of the esophagus and of the upper part of the intestinal tract.

Since I have been advised that the other gentlemen will not consider the surgical diseases of the stomach, it has seemed desirable, in order to make my remarks more comprehensive, to briefly mention the characteristics, clinical history and diagnosis of the conditions before presenting the treatment; and to avoid useless repetition I will leave the description of the various operative measures until the last.

CONGENITAL MALFORMATIONS.

Congenital malformations of the stomach have been

observed frequently, but the character of the conditions has been varied. Congenital malposition may be present and is most commonly connected with congenital defects in the diaphragm or congenital abdominal fissure. A septum dividing the stomach into two chambers more or less completely has been observed, and congenital or acquired constriction of the stomach may give rise to an "hour-glass" shape. The acquired constriction is the result of cicatrized ulcers.

Prolapse of the gastric mucous membrane through the umbilicus has been observed by Tillmans.¹ The same author mentions congenital atresia of the pylorus as of very rare occurrence. A condition of marked congenital hypertrophy of the pylorus has been observed in several instances and has been the subject of special investigation by several, including Dr. John Thomson of Edinburgh, whose valuable contribution, fortified as it is by the result of postmortem and microscopic examination, forms an invaluable addition to the literature of gastric diseases.²

The symptoms are those of pyloric stenosis and death is from starvation. Thus far surgical measures have apparently not been resorted to, but as a probable diagnosis can now be made, there would seem to be no reason why gastroenterostomy or pyloroplasty, or perhaps gastrotomy with dilation, should not be of service in this condition, not only as a palliative but also as a curative measure. (Kammerer has since collected four successful cases.³)

Wölfler was the first to operate for marked "hour-glass" contraction. In 1894 he made an anastomosis between the two chambers—gastroanastomosis.⁴ Up to date the operation has been performed six times with one death.⁴

WOUNDS.

Wounds of the stomach are justly classed with the most serious injuries of the body. MacCormac gives the mortality-rate of wounds as 99%.¹ The principal symptoms are shock, vomiting of blood, and severe epigastric pain, to be followed with fever and peritonitis. The more distended the stomach the more unfavorable the prognosis. That penetrating and perforating wounds are not always fatal even without prompt surgical closure was demonstrated by the celebrated case of Alex. St. Martin, treated by Dr. William Beaumont, in this city in 1822, and who subsequently became the subject of the exhaustive experiments and observations which placed the name of Beaumont on the list of our great physiologists. Both MacCormac and Tillmans have also reported cases of bullet wounds, and Larrey and Archer saber wounds of the stomach, which have recovered without operation.¹

In those cases in which death does not rapidly supervene from hemorrhage or septic peritonitis, abscesses may result, which may be relieved by modern operative measures. There can be no question but that early celiotomy, with accurate suture of the gastric wound and careful toilet of the abdominal cavity, will greatly reduce the mortality of wounds of the stomach.

STENOSIS OF THE ORIFICES.

Stenosis of either the cardia or pylorus may result from cicatrization of an ulcer or a wound, from hypertrophy of the pyloric musculature, or from the growth of malignant or benign neoplasms. Malignant growths demand resection for their removal or the formation of a fistula for the relief of their most distressing symp-

toms. Nonmalignant stricture of the cardia can be most readily reached through the stomach. Gastrotomy with immediate dilation, or gastrostomy with immediate or later dilation, is indicated.

Nonmalignant stenosis of the pylorus can be treated by dilation—pylorodiosis, pyloroplasty or gastroenterostomy. Loreto has practised dilation after gastrotomy in cases of nonmalignant stricture of the pylorus with considerable success since 1882,⁴ but the statistics of Barton⁵ show a mortality of 10 in 25 published cases, which is greater than that of pyloroplasty which is more likely to be permanent in its effect. Hahn dilates the pylorus without opening the stomach by invaginating the anterior wall on the dilating finger. This procedure, while comparatively safe, can obviously be of value in only the mildest cases.

Pyloroplasty has a mortality of about 10%,⁴ and while it is usually effectual, the condition demanding its performance may return. When the mass is very extensive or thick or bound down by many adhesions, the performance of gastroenterostomy is to be preferred. The low mortality, the ease and quickness of its performance and the results of gastroenterostomy make it the operation of election, and unless the conditions are very favorable for pyloroplasty, gastroenterostomy should always be performed.

DILATION.

Dilation of the stomach is usually indicative of muscular atony and functional inefficiency of that organ. While in the vast majority of cases dilation is secondary to some chronic diseases of the stomach or to obstruction on the pylorus or duodenum, it does occasionally develop as the result of overloading of the stomach, and as a result of chemical insufficiency resulting in fermentation and muscular insufficiency. It may also be due to adhesions to other organs or to generally impaired nutrition as observed in anemia, tuberculosis, etc.

In addition to the general symptoms of chronic gastric and intestinal disturbances, the symptoms of the primary disease and the individual's personal history, the vomiting at long intervals of a large quantity of undigested food is characteristic. As local measures, including lavage, have proved ineffectual in many cases, they may have been, as a last resort, referred to the surgeon, in the hope, no doubt in many instances, that even if the operation did not benefit, it might interrupt the long period of suffering.

The medical treatment of gastric dilation should be largely dietetic and antiseptic. Frequent feedings of small quantities of concentrated and easily digested foods with lavage and the use of innocuous antiseptics will frequently effect wonderful improvement and even relief of the condition. To Küssmaul is due the credit of introducing the lavage method of treatment in 1867.⁶ It lessens the weight, removes the mucus and products of fermentation, and affords a means of cleansing and locally treating the mucous membrane.

Gastroplication or "reefing" of the stomach wall, as first practised by Bircher²⁶ in 1891, has been resorted to in a number of cases of simple dilation with encouraging results. The mortality rate of the operation itself has thus far been nil as far as I have been able to learn. If the dilation be secondary to pyloric obstruction, that obstruction must be overcome by divulsion after a gastrotomy or gastrostomy, or circumvented by a gastroenterostomy which is by far the most rational and successful procedure.

GASTROPTOSIS.

Gastroptosis may be present as a single affection, but as a rule it is attended by ptosis of other abdominal organs, particularly the colon and the small intestines. Gastroenteroptosis is a peculiar affection and dependent largely upon 4 factors: Weakened attachments, increased weight, pressure, and lessened abdominal support. It is frequently accompanied by dilation, and in many instances is undoubtedly caused thereby; or both may be due to the same general state of malnutrition. It occurs in persons of large, flabby, relaxed and pendulous abdominal walls, and in thin, pale, neurasthenic individuals, particularly females. In thin persons only is the condition productive of marked symptoms. Pain, indigestion and vomiting, with chlorosis, headache, palpitation, nervousness, etc., form the common group of symptoms. Palpation and inflation usually demonstrate not only a downwardly displaced stomach, but frequently a dilated viscus as well.

Rest in bed, with massage and proper diet, will relieve many of these patients of their distressing symptoms. If the dilation is great, lavage and even "reefing" may be required. If the displacement is marked, gastropexy is indicated, and if accompanied by dilation, both operations should be performed. Gastropexy is of value in relieving the symptoms of a displaced stomach, but to be permanently beneficial, reduction and fixation of any other displaced organs should be performed and attendant constitutional and local conditions should be given proper treatment subsequently.

ULCER.

Both Ewald and Welch have made careful postmortem investigations into the frequency of round or peptic ulcer of the stomach, and have estimated that it occurs in fully 5% of mankind.⁵

The presence of this ulcer seems dependent upon lowered vitality of the gastric mucosa, as by disturbance of the circulation, etc., impoverishment of the blood, as in anemia and chlorosis, and the presence of an excess of hydrochloric acid in the gastric juice. Lowered vitality and local resistance with increased digestive power of the gastric juice would naturally result in a digestion of the stomach-wall with the production of an ulcer—a peptic ulcer.

It occurs in females 50% more frequently than in males, and while 75% of all cases occur between the ages of 20 and 60, no age is exempt. The greatest number of cases are observed in females between 20 and 30, and in males between 30 and 40, but the total observations are nearly equally divided between the 4 decades mentioned. It is most common in servant-girls, dressmakers, and women affected with anemia, chlorosis and menstrual disorders, and in men employed in occupations wherein the stomach is subjected to pressure, as first noted by Habershorn⁵ and in alcoholics and those afflicted with arteriosclerosis. Rasmussen holds that any pressure of the costal arches induces anemia and atrophy of the gastric mucosa.

The ulcer is usually single, but may be multiple and is most frequently situated, according to Frazier,⁷ as follows: 52% on anterior wall; 31% near lesser curvature; 27% near the cardia; 13% near the pylorus; and 8% on the posterior wall.

The ulcer varies from 1 to 10 cm. in diameter, and Peabody⁸ has reported one 10 by 19 cm. in size. It may be superficial or deep with a tendency to destruc

tion of adjacent tissue. This destructive tendency leads to erosion of the bloodvessels with the production of hemorrhage in fully 50% of the cases, and in over 6%, according to Welch,⁵ it results in perforation.

If the perforation is anteriorly, general peritonitis usually follows; if posteriorly or at the lesser curvature, subphrenic abscess in the cavity of the lesser omentum is to be expected; while if the perforation is preceded by a plastic peritonitis with adhesions the establishment of a fistula into one of the abdominal viscera or thoracic cavities could occur.

From the foregoing data it would appear that over 50% of the cases of ulcer are attended by hemorrhage or perforation and, therefore, the condition is to be regarded as a truly serious one.

The diagnosis may be easy, but it is frequently exceedingly difficult, not to say conjectural. It is based upon the presence of some of the foregoing predisposing factors and upon the existence of pain, hemorrhage and vomiting. The pain is usually localized, varied in character, and aggravated by taking food; but it may come at irregular intervals, and even be relieved by eating or pressure.

The hemorrhage which is so common in ulcer, may appear in small quantities or be very profuse. It may appear in the vomitus or in the stools. Sudden vomiting of a large amount of bright red blood is quite characteristic of ulcer. The vomiting usually occurs after meals, and affords relief from pain. Localized epigastric tenderness is often marked, but in other cases firm pressure alone seems to relieve the suffering. The symptoms may subside and even disappear with healing of the ulcer, but it may recur, or the cicatrix may distort the conformity of the stomach, or be painful, or even be the site of a carcinoma.

In the treatment of gastric ulcer, medical measures like ice, astringents, opium, etc., with absolute rest are indicated for first and second attacks, according to Rodman,⁸ but after the second attack and particularly in all cases of recurrent hematemesis, operative measures are positively demanded. Operation during acute hematemesis, and particularly the first, has been very unsatisfactory. Robson¹³ gives the mortality as 64.2%, which he contrasts with 5% to 10% mortality of acute hemorrhage treated medically. The reflex effect of hot water enemata at a temperature of 112° to 120° F. has been advanced and successfully employed by Tripiér in a number of cases.⁹

A sufficient number of operations have now been reported to warrant some definite statements as to the advisability and success of operating. Rodman⁸ collected 31 operations for recurrent or chronic hemorrhage with 6 deaths, a mortality of 19.3%, and he quoted Robson as reporting a mortality of 16.4% in all operations for gastric ulcer and of only 10.5% in chronic cases. These statements are certainly most encouraging, and with early diagnosis and operation at the proper time, these figures should be materially reduced.

Of the various methods which have been employed partial gastrectomy or pylorotomy, depending upon the location of the ulcer, and the ligation of the mucosa *en masse*, have been the procedures of direct attack most successfully employed. According to Tillmans¹ and Keen,¹⁰ Czerny was the first to successfully excise a gastric ulcer in 1882, but Greig Smith¹¹ and Curtis²⁶ give the credit to Rydygier in 1881, while Wier and Foote¹² ascribe it to Kriege in 1892. Mikulicz appears to

have been the first to operate by treating the ulcer directly in 1887.⁸ He combined cauterization with pyloroplasty.

When the nature of the process is considered it will be appreciated that cauterization or ligation of the bleeding vessel alone does not meet all the surgical indications presented.

Gastroenterostomy is rapidly gaining favor as the elective operation for ulcer with chronic hematemesis. By placing the stomach at rest and draining off the over-acid gastric juice, it provides the two essential factors for healing of the ulcer. Robson¹³ is particularly favorable to the procedure.

In cases with profuse hemorrhage some local measures seem demanded, and anyone of the foregoing methods, particularly when combined with gastroenterostomy, would be indicated.

In cases of acute perforation, immediate gastrorrhaphy is unquestionably demanded. Lund has shown that during the past 3 years operations within 12 hours gave a mortality of only 14%, and within 24 hours 27%, which contrasts markedly with the earlier statistics, which showed a mortality of 50 to 90%.⁷

The investigations of Greenough and Joslyn¹⁴ revealed the fact that only $\frac{1}{2}$ of the 80% of ulcer patients discharged from the Massachusetts General Hospital as relieved, remained well at the end of 5 years, which would show that permanent relief failed in 60%, and that 20% of the total number died.

CARCINOMA.

Excepting the uterus, primary carcinoma occurs in the stomach with greater frequency than elsewhere. Welch¹⁶ found it present in over 21% of cases. It is most common in males, while over 75% of the cases occur between the ages of 40 and 70. It may occur in the young, Sutton having reported a case in a girl only 13 years old.¹⁶ Heredity seems to be a predisposing factor. Some have thought that gastritis, traumatism and peptic ulcer were also important factors in its production.

The varieties occur in the following order of frequency: Cylindrical-celled, encephaloid, scirrhus and colloid. Welch determined its location in 1,300 cases as follows: Pyloric region 791, lesser curvature 148, cardia 104, posterior wall 68, diffuse 61, greater curvature 34, anterior wall 30, fundus 19. Secondary cancer may occur in the stomach, but Welch¹⁵ was able to collect only 37 cases, 17 of which were secondary to carcinoma of the breast. Metastasis is frequent, particularly in the lymphatic glands and in the liver.

The first symptoms noted are usually those of chronic gastritis, anorexia, distress, flatulence, and occasionally nausea and vomiting. These are in turn followed by anemia, loss of weight and strength, and cachexia. Pain may or may not be present. Hemorrhage is usually slight, and the vomitus has a dark "coffee-ground" appearance. The vomiting is most common when the tumor is at the cardia or pylorus.

The absence of free hydrochloric acid is no longer considered pathognomonic, but rather only a confirmatory evidence of cancer. Boas¹⁷ and others hold that the pressure of free lactic acid in the stomach, sufficient to give the Uffelmann reaction, *i. e.*, the canary-yellow tint to the carboferric chlorid solution, is of greater significance.

Progressive anemia of the secondary pernicious type is most commonly present. The blood-count is rarely

below 50%, but the hemoglobin is low, and leukocytosis is usually marked.

Examination commonly reveals the presence of a tumor in the epigastric region, and if it is located at the pylorus, dilation of the stomach also. According to Senn,¹⁶ carcinoma of the stomach, with few exceptions, proves fatal within a year.

The treatment of carcinoma of the stomach is palliative and radical. To enable radical resection measures to be successful the diagnosis must be made early and the case subjected to operation before regional dissemination of the process has occurred. Resection of the pylorus, of the stomach-wall, and of the whole stomach have their indications and scope of employment, but statistics will demonstrate the comparative uselessness of radical measures, except when the disease is early recognized, and when it is localized and in a readily accessible part of the organ. The mortality of pylorotomy is given as from 20 to 70%,¹⁸ and of extensive or total gastrectomy from 28 to 33%. The fact that the immediate mortality of these operations is so great is due largely to the lateness with which these patients are sent to the surgeon and their terribly reduced condition. That many of those who survive the operation finally succumb to the disease but emphasizes the vital importance of early diagnosis and early radical operation.

It is in this class of cases that a surgeon can afford to occasionally err in diagnosis and even to perform a needless operation rather than to allow the golden opportunity for a possibly successful radical operation for a beginning carcinoma to escape. The man who is not willing to assume the responsibility of a probable diagnosis under such circumstances is not worthy the title and honor of being a surgeon. Exploratory laparotomy for diagnostic purposes is recognized as a justifiable procedure in pelvic and intestinal surgery, and surely it is equally justifiable, and, in our opinion, imperatively indicated in the obscure diseases of the stomach.

The radical operations of the stomach require great skill and dexterity, and a degree of familiarity with abdominal surgery possessed by comparatively few, for their proper and yet essential rapid performance. The presence of local dissemination, unless limited to a few very accessible glands, contraindicates radical measures. In such cases lavage with salol and bismuth should be employed to prevent fermentation and dilation, and their resulting malnutrition.

The palliative operative measures consist in making a gastrotomy for disease of the cardia or a gastroenterostomy when the tumor is located in the pyloric region or lesser curvature. These operations are in no sense curative, but are performed for the sole purpose of prolonging the patient's life and relieving the terrible suffering incident to a death by starvation.

The mortality of these operations for cancer has been reduced by modern methods from over 30% to 10.5%, but even the greater mortality is as nothing compared to the comfort which is afforded those who survive. When performed early and under favorable circumstances the mortality should be practically nil.

FOREIGN BODIES.

Foreign bodies gain access to the stomach through the mouth and occasionally accidentally as the result of a wound or the falling into the stomach of some insoluble mechanism used for performing gastroenterostomy.

The list of articles which have been removed from the stomach or intestines after passage through the stomach is quite remarkable. Pins, needles, nails and balls of hair are comparatively common, but considerable pieces of wood and glass, sets of teeth, keys, pocket knives, table forks and knives, etc., have been successfully removed by gastrotomy or enterostomy. The more irregular the shape, the more pointed the article, or the more pain and other symptoms produced, the greater the demand for immediate operation. The use of the x-ray is of special value in determining the presence, nature, location and quantity of such articles contained in the gastrointestinal tract.

DISEASES OF OTHER ORGANS.

The utilization of the stomach as a route for attack upon disease of the esophagus particularly has been most satisfactory. By the performance of gastrotomy, disease of that organ can be investigated often by direct digital examination, and nonmalignant strictures may be detected and divulsed or divided. In malignant disease of the esophagus, and in complete stenosis of that organ, gastrostomy affords an avenue for the proper nourishment of the individual.

In like manner gastroenterostomy establishes a channel by which food may pass directly into the intestines below an obstruction in the upper intestinal tract. In this manner the local disease is isolated from the food current, and if it is of a malignant character, the rest lessens the rapidity of the growth, while if the obstruction is of a nonmalignant character it may effect permanent relief.

OPERATIONS UPON THE STOMACH.

As an essential to successful operating upon the stomach this organ must be both empty and clean. Preliminary lavage with warm water and boric acid solution should be emphasized. It is good practice to utilize rectal feeding *before operation* in order to accustom the rectum to its new duties and to derive the benefit of increased nourishment. The bowels should be thoroughly emptied and the general condition of the patient looked after with special care, as his bodily vigor is often greatly reduced.

The surgical operations performed upon the stomach consist of gastrotomy, gastrorrhaphy, pyloroplasty, pylorodiosis, ligation of mucosa *en masse*, gastrostomy, gastroenterostomy, gastroanastomosis, pylorotomy, gastrectomy, gastroplication, gastropexy and gastrolisis. Of these 13, several have numerous modifications, while some must be preceded by gastrotomy.

GASTROTOMY.

The operation of simply opening into the stomach has been most frequently made for the removal of foreign bodies, but at the present time it is claiming more attention as a preliminary operation to those directed to the diseased areas themselves. In ulcer when it is proposed to cauterize or ligate the area, and also when it is desired to explore the stomach, or the patency of its orifices or the lower part of the esophagus, as well as when the dilation of stricture of either orifice is contemplated, it is, of course, necessary to first perform celiotomy and gastrotomy.

The abdominal incision should vary with the location of the disease; if at the pylorus, either median or vertical incision at outer border of right rectus; or if in other parts of the stomach, an incision parallel to and

about one finger's breadth from the edge of the left cartilages will expose the whole viscus to good advantage.

The incision into the stomach is usually made in the anterior surface after the peritoneal cavity has been well protected by hot moist pads, and after controlling the hemorrhage of the stomach-wall the remaining contents of the stomach are removed. After exploring the stomach, removing the foreign body or treating the pathologic condition found, the wound is closed by gastrorrhaphy. Gastrotomy was first successfully performed in 1602 by Mathis and again in 1635 by Schwabe.¹⁹

GASTRORRHAPHY.

Gastrorrhaphy means the suturing of the stomach-wall. Some writers use the term to indicate suturing of the stomach to the abdominal wall—gastropexy. Some prefer making a continuous suture of the mucous membrane and other of the muscular and serous coats before applying the Lembert suture. Still others content themselves with the application of the simple Lembert suture. There would seem to be no reason to doubt but that in an organ so liable to straining of the line of sutures by vomiting, special precaution against leakage should be taken. There is certainly good reason for applying two rows of sutures in all gastrorrhaphies, and the use of at least one continuous suture is in our opinion demanded.

PYLOROPLASTY.

This procedure consists in the making of an incision through all the coats of the pylorus parallel to the long axis of the stomach and the suturing of the same at right angles thereto. The Lembert suture is employed and may be preceded by a suture of the mucosa, or fortified by a second row of sutures. It is known as the Heineke-Mikulicz operation, both having simultaneously devised the same method in 1886-7. The mortality is given as 10%, but this seems altogether too high with our present technic.

PYLORODIOSIS.

Loreta's operation for dilation of stenosis of the pylorus is equally applicable and probably even more indicated in stenosis of the cardia. It consists in the performance of gastrotomy and the dilation of the stricture by the insertion of one or two fingers or the use of the uterine dilator.

LIGATION OF MUCOSA EN MASSE.

In operating for ulcer, its location is frequently determined to be in a position not admitting of ready excision. For this class of cases and particularly when the stomach is fixed by adhesions, the ligation of the mucosa *en masse* has been successfully practised in several instances. Unless the area is supported by external Lembert sutures perforation is liable to occur, as demonstrated by Andrews and Eisendrath.²⁰ If to this should be added gastroenterostomy all surgical indications would seem to be filled.

GASTROTOMY.

As has been previously indicated, this is an operation establishing a fistula to admit of the repeated dilation of stenosis or to prevent starvation. It was first performed by Sedillot in 1849.¹⁰ Many methods and modifications have been proposed to prevent leakage. Those

providing a valvular orifice have apparently been most satisfactory. The oblique incision parallel to the left costal arch is usually employed.

Witzel's method (1891) consists in passing a medium-sized, soft catheter through a small opening into the stomach and then burying it in the gastric wall in a vertical position by sewing the peritoneum over it for a distance of 5 to 6 cm. (2 to 2½ inches). The stomach is then sutured into the abdominal wound.

Frank's method, variously called Albert-Frank-Kocher and Ssabanajew-Frank method, consists in making a valve out of a small cone of the stomach-wall. The oblique incision is made and a cone of the stomach pulled out and its base sutured to the parietal peritoneum. A second incision is made just above the rib-margin, the bridge of the skin elevated and the cone pulled up beneath it and the apex sutured into second wound. Tube is inserted and first skin-wound closed.

Marwedel's method (1896) resembles Witzel's in all respects, but he incises the serous and muscular coats for 5 cm. (2 inches), then passes the tube through the mucosa and buries it by closing the incision in the stomach-wall.

Kader's method (1896) produces a funnel projecting into the stomach by suturing two sections on either side of a tube placed vertically into the stomach. Each pair of sutures increases the amount of peritoneum about the tube and further depresses the point of entrance of the tube.

E. J. Senn's method (1896) consists in making an automatic valve out of the stomach-wall by constricting a cone near its apex with purse-string suture and after incising the apex inverting it into the stomach and securing it there by Lembert suture.

The methods of Kader and Marwedel are most popular at the present time, but the method of Senn would seem to be an improvement over the Kader procedure.

GASTROENTEROSTOMY.

The establishment of a connection between the stomach and intestine was first performed by Wölfler in 1881,¹⁰ and is indicated in the several conditions previously noted, but particularly in pyloric obstruction, cancer and ulcer.

While the mortality has been about 10% in the non-malignant, and about 30% in the malignant conditions, there would seem to be no good reason why, with our present technic, the mortality of this operation when early performed should not be practically nil. There is certainly nothing about the operation itself which should, in careful and dextrous hands, cause any mortality.

The anastomosis should be made on the posterior wall of the stomach at its lowest point and the union effected by a Murphy button or suture.

Masse¹ has demonstrated that regurgitation of bile is of no consequence, but to avoid the possibility of annoyance Braun suggests the making of a simultaneous duodeno-enterostomy.

The incision for gastroenterostomy is made in the median line above the umbilicus, the stomach is located and then the upper part of the jejunum is found and either turned over the transverse colon or a small slit is made in the mesocolon and the posterior wall of the stomach seized and both are brought into the wound. If the sutures alone are to be employed a continuous suture should be applied in the most posterior part of the area of intestine and stomach to be approximated,

before either viscus is opened. After making the incision in both organs it is best to make a continuous suture approximation of the two wound edges and then to carry the first suture completely around the second one. This is a rapid and effectual method.

If a Murphy button is to be employed a small incision is to be made in one viscus, two lateral sutures introduced as advocated by Murray, half of button introduced and suture tied. After the same is done on the other side, the button is closed. This can be fortified by a row of sutures, but if the rent in the mesocolon is closed about the point of anastomosis it affords sufficient additional protection. The fact that this operation with a Murphy button and a continuous row of sutures can be performed within 10 minutes will commend its use until some better mechanism is devised. It would seem that having the lower half of the button larger than the upper half would prevent its dropping into the stomach, and thus avoid an objection which has been advanced against its usage. If time is an object, the button should be employed, otherwise the operator can choose his method, as both are excellent. Chaput, McGraw, Sonnenburg, and later Kocher have devised methods for the formation of valvular openings to prevent regurgitation. In 1898 Podrez²¹ performed gastroenterostomy by inserting two sutures at right angles and tying tightly to produce pressure necrosis. Sokoloff²² reports failure in 2 out of 4 cases. If it is to be successful, elastic ligatures should be employed as advised by McGraw in 1891.²³

GASTROANASTOMOSIS.

Gastroanastomosis or gastrogastrostomy was first performed by Wölfler in 1894, and independently by Watson in 1896,³ for the relief of marked "hour-glass" contraction of the stomach. Its technic is identical with gastrectomy or gastroenterostomy.

PYLORECTOMY.

This procedure was advised by Merrem in 1810,¹⁶ Pean was the first to perform it in 1879—while Billroth performed the first successful operation in 1881.¹

The mortality of the operation has been so great that its performance would seem to be rarely justifiable, but the present results of abdominal and gastric surgery would seem to warrant a more favorable immediate prognosis than was formerly given.

The oblique incision of Billroth directly over the tumor or an incision along the outer edge of right rectus is made, pylorus liberated and pulled well into the wound. The section should be made from 3 to 5 cm. (1½ to 2 inches) beyond the tumor. After excision the duodenum can be sutured into the gastric wound by double row of Lembert sutures, or the latter can be closed and the anastomosis of the duodenum into the posterior wall effected, or both wounds can be closed and a gastroenterostomy performed.

GASTRECTOMY.

The technic of partial gastrectomy is identical with that of pylorotomy. Robson collected 14 cases of extensive resection with mortality 28.5%. In total gastrectomy, the section of the duodenum is first made and then the omenta and ligaments divided between clamps. The stomach is then cut off from the esophagus, leaving a little of the stomach-wall if possible. The duodenum is then united to the esophagus by suture or a Murphy button.

Schlatter successfully performed complete gastrectomy in September, 1897. Death occurred 14 months later from general carcinomatosis. Since that time the operation has been successfully performed by Brigham (patient well 2 years after), Delatour (patient well 17 months after), Richardson (patient lived 11 months and died from local recurrence), MacDonald (patient well 18 months after), and Harvie (just reported²⁴). Death on the table or within 36 hours occurred in the cases of Chavasse, Kobb and Bernays. Of the 6 successful cases, 2 have died in 14 and 11 months. Four are still living.

A mortality of only 33% for the operation *per se* is certainly remarkable, and this fact, with the ultimate results presented, demonstrates the practicability of this life-prolonging and life-saving measure. The remarks made under the treatment of carcinoma concerning the importance of early diagnosis and early operation need no better proof as to their correctness than the above data.

GASTROPLICATION.

Gastroplication or "reefing" of the stomach-wall, as first practised by Bircher in 1891,²⁵ is effected by the insertion of two or more rows of sutures in such a manner as to approximate two broad areas of the anterior surface of that organ. The sutures include only the serous and part of the muscular coats.

GASTROPEXY.

Gastropexy consists in the fixation of a displaced stomach in its normal position. This is usually accomplished by the coaptation and fixation of a considerable area of the stomach-wall to the anterior parietes by several sutures. In some cases it may be possible to reef the lesser omentum. It is usually necessary to fix the colon and other displaced organs at the same time.

GASTROLYSIS.

The term gastrolisis is used to designate the operation of dividing adhesions which may fix or distort the stomach. If the adhesions are cord- or ribbon-like its performance is both easy and safe, but if they are broad and extensive their removal may compromise the gastric wall sufficiently to necessitate resection.

A CASE OF LIGATURE OF THE INNOMINATE ARTERY FOR ANEURYSM.*

By S. P. DELAUP, B.Sc., M.D.,

of New Orleans.

Visiting Surgeon to Charity Hospital.

Triple ligature of the innominate artery for high innominate and carotid aneurysm and also axillo-subclavian aneurysm, followed by a simultaneous double ligature of the common carotid and vertebral arteries at a subsequent operation. Death from exhaustion on the twenty-first day.

The case which I submit for your consideration is at the same time rare and important, and further should excite your special interest in that the first successful case was performed in this city in 1864. It will, no doubt, give rise to criticism; but do we not learn by our failures as much as by our successes, and does not the history of medicine, surgery especially, show that it is made up of mingled failures and successes? So, although it is my misfortune to report a failure, I trust my experience will be of some service to those surgeons who will be bold enough to undertake this hazardous operation.

On considering the history of this operation, since it was first performed by Valentine Mott, in 1818, one is so forcibly struck by the almost unbroken record of fatal results as to question its advisability.

It must be remembered, however, that the majority of the recorded cases belong to the preaseptic period, and some of the more recent cases have succumbed from faulty asepsis. Hence, viewed from the light of modern surgery, the operation of ligature of the innominate artery is not only justifiable, but feasible, though it still remains one fraught with danger. I cannot help believing that the results obtained in the next series of cases will be much more encouraging.

History of the Case.—A negro, 58 years of age, is admitted in my service at the Charity Hospital, on June 2, 1900. He is a man of good development, well nourished, and presents a pulsating tumor, the size of a large orange, on the right side of the chest. In his right shoulder, he complains of constant pain, fulness and throbbing, which have existed with varying intensity for several weeks before admission. He states that pain in his shoulder is the first symptom that called his attention to his present trouble, and that occurred in January. Two months later he noticed a sense of throbbing at the upper part of the right side of the chest, and very soon afterwards loss of power in the right arm. A swelling below the clavicle slowly made its appearance and has gradually grown to its present size. The pain likewise kept pace with the growth of the tumor, and is now so intense as to cause him to seek relief.

On the forehead, between the superciliary ridge and right above the nasal spine, a depression and scar are very conspicuous. When a boy of 16 years he was struck with a hatchet and thereby suffered a fracture of the frontal bone. This injury seems to have caused no bad effect.

A somewhat indefinite history of previous apoplexy is elicited. The attack occurred eight months ago, he was confined to bed for about one month and was unable to use his left upper extremity for about the same time. He soon recovered and resumed his work as a laborer.

His family history is easily told, inasmuch as negro hospital patients, as a rule, are unable to give any information on that point.

A physical examination shows the existence of an aneurysmal tumor behind the right pectoral muscles, filling the bottom of the axillary space and extending to the right clavicle. The cutaneous veins over that region are much dilated. A

systolic bruit is distinctly heard, and an expansive thrill readily made out.

The heart-area is enlarged, and the apex is fully $\frac{1}{2}$ inch to the outer side of the mammary line. Two murmurs are discerned: one at the apex with the first sound, the other at the second right interspace with the first sound. No difference can be detected between the arteries in the wrists, either in strength, fulness, or rhythm.

The radial and ulnar arteries on both sides are very superficial and their atheromatous condition can be felt. There is no edema of the right hand. Pressure with the thumb on the subclavian artery over the first rib obliterated the radial pulse and pulsation in the tumor.

As well as can be ascertained the lungs are normal. Nothing abnormal is detected from an examination of the abdominal organs. The urine contains a trace of albumin, otherwise there is nothing noteworthy. The veins of the lower extremities have a tendency to varicosity. The pupils are regular. There is no cough, and no laryngeal irritation. Temperature up to 100° nearly every day.

Attempts were made to secure sphymographic tracings of the right and left radial pulse, but no record could be

FIG. 1. Appearance of tumor, enlarged veins, etc.

obtained. The diagnosis of an idiopathic axillo-subclavian aneurysm depending on a general arteriosclerosis is made.

The patient is placed in bed and put on a low diet combined with potassium iodid in large doses. An ice-bag on the tumor is also used. At the end of the first week the tumor appears to be larger. At the end of the second week, the pulse still continues high, the tumor increases in size, while the pain in the arm is unbearable; the patient lies in bed with the arm outstretched and begs for relief. The medical treatment has thus far been without any appreciable result. I then had a consultation with Drs. Bloom and Parkham, and as the result of the consultation it was decided to attempt operation upon the third portion of the subclavian, and in the event of that proving diseased upon the first portion, and as a last resort upon the innominate, and also if practicable to complete the operation with a ligature of the axillary artery above the subclavian.

Operation—On June 16, with the cooperation of Drs. Bloom, Parkham, Marion, Souchon, and other members of the hospital staff, the following operation was carried out:

The patient having been chloroformed was placed in the usual position on his back, with the shoulders elevated and

* Read before the Orleans Parish Medical Society, November 24, 1900

the head well drawn towards the left side. Having drawn the cervical skin upwards I made an incision 3 inches in length, extending from the outer border of the trapezium to the posterior border of the sternocleidomastoid muscle. The skin flap with the superficial fascia and platysma muscle was drawn back and the cellular tissue was dissected away, exposing the upper or supraclavicular portion of the sac. The fibers of the subclavius muscle were pushed upwards, carrying with them the dilated supraclavicular vein. On further dissection I discovered that the aneurysm not only

FIG. 2. Aneurysm exposed.

involved the entire third portion of the subclavian artery, but extended to the second portion. Ligature at either portion was out of the question. The cutaneous incision was then prolonged to the middle of the manubrium. The sternomastoid muscle was divided close to its insertion into the clavicle and sternum. In the cellular tissue now exposed a medium-sized vein was severed between two ligatures. The sternohyoid and sternothyroid muscles were also divided.

The artery exposed to view was of very large size, so much so, indeed, that some of those present thought I had reached the innominate artery. The vessel filled the field of operation so completely that an incision of the clavicle and sternum was decided upon.

The inner third of the clavicle was carefully dissected and its periosteum peeled off. With a Gigli saw section was made from below upwards. The sternal end was freed with care and the section removed without injuring the delicate structures behind. A flat retractor was slid underneath the manubrium to protect the underlying parts. The right sternoclavicular articulation and the right half of the notch of the manubrium were cut out with the rongeur forceps, thus enabling me to place the ligature in a far more satisfactory manner than if the ligature was slid down, in the dark, behind the sternum.

I now went further down in search of the bifurcation, but this was an extremely tedious and anxious proceeding owing

to the dilated and diseased condition of the artery. It was found impossible to expose the first portion of the subclavian artery; it could only be felt with the finger deep in the wound behind the dilated innominate artery.

I had here to deal with a fusiform aneurysm of the innominate artery involving the bifurcation and extending up and on the common carotid in addition to the subclavian aneurysm. The artery near its origin from the arch was about double its normal size and at its upper part was fully $1\frac{1}{2}$ inches in diameter. As far as could be ascertained the innominate aneurysm continued upwards as the common carotid, forming one continuous sac. The first portion of the subclavian artery was hidden behind the aneurysmal tumor, and could not be exposed; to the finger it felt of normal size. It was believed that enough of the innominate was fairly healthy to place a ligature between the fusiform aneurysm and the aorta. The left innominate vein above and the right pneumogastric and phrenic nerves and internal jugular vein, on the side, were plainly seen in the wound and drawn out of harm's way. The sheath of the innominate artery could not be separated as it was closely adherent throughout the extent of the artery. The index finger was passed down to the arch of the aorta below and around the innominate artery, near its origin.

Three ligatures, two of kangaroo tendon and one of braided silk, were applied in the following manner: I placed the first kangaroo tendon a little over an inch above the aorta, and before tying tested the effects of pressure upon the artery between my finger and the ligature, slightly lifting the artery from its bed, and finding a diminished pulsation in the radial artery and aneurysm I secured the ligature with 3 square knots, using moderate firmness only, with the

FIG. 3. Aneurysm exposed.

idea of not rupturing the coats of the vessel. This ligature was not tight enough to serve as a buffer and protection for the second one. The second ligature of kangaroo tendon was placed about a half inch below the first and about three-fourths of an inch from the arch of the aorta. Gradually it was drawn tighter until the circulation was completely cut off. A third kangaroo tendon ligature was tied in the same place to reinforce the other two, but it broke. I then used a braided silk ligature that com-

bly rupturing the coats. The ligatures were all passed from within outward and were put in position with a large aneurysmal needle. It was my purpose, if possible, to ligate the common carotid and vertebral arteries, but the patient, who had taken the anesthetic admirably well and had been under its influence for over 2 hours, now gave evidence of shock, so it was deemed advisable to close the wound as rapidly as possible and defer further operation to a more propitious time. The overlying muscles were sutured with kangaroo tendons in approximately their original positions, and the edges of the wound were brought together with silkworm-gut sutures. The pulsation was gone from the subclavian aneurysm and right radial artery. The right upper extremity from finger to shoulder was wrapped in sheets of wadding and bandaged to maintain its temperature. The patient was at once put to bed, and was in fairly good condition. The operation lasted over 2 hours; it was done with deliberation and care, and was practically bloodless. The preliminary operation for exposure of the third portion of the subclavian artery, the excision of the clavicle and sternum, and the dissection of the aneurysm of the innominate artery, were procedures that consumed considerable time and account for the tediousness and duration of the operation. A slight pulsation in the right radial artery is detected at 6 P.M., about 4 hours after the operation. The patient is drowsy and does not recover easily from the anesthetic. Has a restless night; nausea and vomiting.

June 17.—A.M., temperature 100°, pulse 110, respiration 30. Patient restless, mental condition dull. A small but distinct radial pulse is felt, synchronous with left radial. There was no pain and no vomiting. He complains of headache.

June 18.—A.M., temperature 99.4°, pulse 104, respiration 20. Mental condition somewhat improved. Marked pulsation is felt over the tumor. P.M., temperature 100°, pulse 114, respiration 18.

June 19.—A.M., temperature 99°, pulse 100, respiration 16. Mental hebetude continues. Tumor decidedly denser and smaller. Bowels moved. Dressings stained with serous oozing. Changed the dressings. Urine: 3% moist albumin, casts. Got up from bed during night to get water. P.M., temperature 100°, pulse 108.

June 20 (5th day).—A.M., temperature 98½°, pulse 100; P.M., temperature 100°, pulse 106. Is comfortable and free from pain.

June 21 (6th day).—A.M., temperature 99°, pulse 100; P.M., temperature 99½°, pulse 110.

June 22 (7th day).—A.M., temperature 100½°, pulse 112; P.M., temperature 99½°, pulse 110. Mental condition unchanged. On changing dressings pus was detected at two sutures.

June 23 (8th day).—A.M., temperature 99½°, pulse 106; P.M., temperature 99½°, pulse 116. Changed dressings. A little purulent matter escaped from the wound. Irrigation with formalin solution and hydrogen dioxid solution was made.

June 24 (9th day).—A.M., temperature 100°, pulse 118; P.M., temperature 99½°, pulse 112. Pulse in right radial is strong and bounding. There is a small sinus which extends downward and toward the sternum, under the skin and 1½ inches deep.

June 25 (10th day).—A.M., temperature 100½°, pulse 108; P.M., temperature 99°, pulse 114. Mental condition improved.

June 26 (11th day).—A.M., temperature 99½°, pulse 104; P.M., temperature 99½°, pulse 112. Restless at night. Mental state is changed in that the delirium is more active and talkative. Has to be restrained and tied to bed. Daily dressings continued.

June 28 (13th day).—A.M., temperature 100°, pulse 110; P.M., temperature 99½°, pulse 96. Mental condition same. Very little pus, but granulations are unhealthy.

June 30 (15th day).—A.M., temperature 98½°, pulse 92; P.M., temperature 99½°, pulse 104. Slight edema of right hand.

July 1 (16th day).—Patient is natural in appearance and feels comfortable. Since the operation his mind has not been perfectly clear, at times there is actual delirium.

July 2 (17th day).—A.M., temperature 98½°, pulse 112; P.M., temperature 99½°, pulse 92. Delirium less active. Wound looks more healthy, sinus appears to be closing. Hardly any discharge.

July 5 (20th day).—A.M., temperature 102½°, pulse 120; P.M., temperature 102°, pulse 116. Nothing to explain elevation of temperature. Patient is quiet and resting comfortably.

July 6 (21st day).—Mr Terry, the interne of the ward, was called at 6 o'clock that morning to see the patient, who had had a slight hemorrhage a few minutes before. Patient stated that he felt weak and chilly. Temperature 100°, pulse 120. One-fourth of a grain of morphin was given and a shot-bag applied over the aneurysm and neck. When I saw him that morning at 10 o'clock he was very weak and his face was covered with perspiration. The hemorrhage from the wound had been easily arrested and little blood had been lost. At that time his temperature and pulse were 100½° and 140° respectively. I was only waiting for the wound to be completely healed before attempting the ligature of the common carotid and vertebral arteries.

In view of the fact that the secondary hemorrhage in these cases usually comes from the distal end of the artery, and that pulsation in the common carotid had been felt three days after the operation, I decided, notwithstanding the patient's unfavorable condition, to re-open the wound and expose that artery, feeling justified in the belief that that vessel was the source of hemorrhage. Remembering also Smyth's brilliant ligation of the vertebral artery, I included it as a possibility in the operation. The patient was placed upon the table and chloroformed. With Dr. Bloom's assistance I made the usual incision along the anterior border of the sternomastoid muscle and readily exposed the right common carotid artery. A silk ligature was applied half an inch below the bifurcation. More difficulty was experienced in exposing the vertebral artery, not only on account of its deep situation in the neck, but owing to the adhesion which had formed since the first operation. The artery was finally dissected out and a silk ligature placed about a half inch from the vertebral foramen. Just as the wound was being prepared for closure, the patient's heart stopped. During the operation very little chloroform had been used, as his condition had been poor, demanding active stimulation. For half an hour artificial respiration was tried, but in vain.

Postmortem Examination.—An autopsy was held an hour after death by myself, but as the body was claimed the examination was limited to the neck and thorax: that is, those parts actually involved in the disease and operation. The original line of incision was practically healed with the exception of a small sinus barely admitting the introduction of a slender probe. The sinus extended toward the sternum and contained at its external end a small elongated clot; presumably this was the channel through which the hemorrhage had taken place.

The clavicular stump was well covered with a mass of fibrin, and the sternal cavity well filled with the same material. The left lung was normal and free from adhesions. The right lung was closely adherent to the second and third ribs about the mammary line, at a place corresponding to the base of the subclavian tumor, otherwise the lung was normal. The pericardium was smooth. The heart was greatly hypertrophied, the left ventricular wall being about an inch thick, all the cavities of the heart, particularly on the left side, were dilated. The valves were thickened and hard. The arch of the aorta was thickened and dilated, the dilation affecting equally the circumference of the artery. Of the large branches springing from it, the left common carotid and subclavian were normal in size but thickened. The innominate artery was a little over two inches in length and at its upper part presented a fusiform dilation that was continuous upwards into the common carotid for about one and a half inches. The innominate artery about its middle part was surrounded by a thick and wide ring of firm cicatricial tissue. No sinus was discovered leading to the lumen of the artery. The entire silk ligature was found lying in the lumen of the artery; the knot was intact and the ligature was held by a posterior segment of the artery. It had

gradually cut its way through the artery and the fibrinous ring about it had been sufficiently organized to prevent hemorrhage from the severed artery. No trace of the kangaroo tendons was found; they had evidently been completely absorbed, the distal and proximal ends of the divided artery were pervious, and it is to be supposed that circulation through the artery had been reestablished a few days after the operation.

The common carotid was found dilated, the lower third forming a part of the innominate aneurysm and the ligature was found half an inch below the bifurcation of the artery. The subclavian artery was found to spring from the posterior aspect of the innominate aneurysm, it was normal in size but atheromatous. The branches of the thyroid axis were all much enlarged, the vertebral was ligated about one inch from its origin, the suprascapular was enlarged to three times its usual size and passed over the upper portion of the subclavian aneurysm. The second and third portions of the subclavian artery and the first and second portions of the axillary artery were involved in the subclavian aneurysm.

The aneurysmal tumor was found to spring from the posterior aspect of the third portion of the subclavian artery and the first portion of the axillary. It was flattened below where it rested on the first, second and third ribs; above it was deeply grooved by the clavicle. A portion of the second rib was absorbed, producing a pathologic fracture.

Portions of the first, second, and third ribs were removed with the attached tumor, together with the heart; the two solid parts, the heart and tumor, being joined together by the first portion of the subclavian artery as by a hyphen. The whole part was taken out en masse.

An incision was made into the aneurysm parallel to its base. It contained a mass of dark, thick clots occupying the cavity. The process of cure was evidenced by fibrinous layers upon the walls and on the inner sides of this coating were masses of coagulum less firm but evidently undergoing consolidation. To summarize it may be said that this case is one of arteriosclerosis affecting the aorta and the large arteries and even the veins, presenting a fusiform aneurysm of the innominate and common carotid arteries, also a sacculated aneurysm of the subclavian and axillary arteries, in which a triple ligature of the innominate artery was applied, followed by nonocclusion of the artery by the ligatures, severance of the artery by the lower ligature with subsequent probable ulceration and slight hemorrhage, the ligature remaining within the artery and the continuity of its lumen being restored, and in which a double ligature of the right vertebral and common carotid arteries was placed at a subsequent operation, followed by death from exhaustion.

In dealing with this case I was fully impressed with its gravity. The various plans of medical treatment, as well as other operative measures besides ligature of the innominate, such as amputation at the shoulder-joint, distal ligature of the subclavian at its third portion, Stewart's method of electrolysis through a wire, MacEwen's needling, had been considered and set aside as impracticable or unsuitable. It was then with a full appreciation that I undertook it, and, notwithstanding the fatal termination of my case, I still believe that ligature of the innominate artery may be safely done.

"The operations on the vessels behind the clavicle and sternoclavicular joint," says Barwell (on Aneurysm, p. 55), "are among the most arduous in surgery, requiring both steadiness and a certain courage. . . . Given, however, that the operation has been performed in a moderately short period, and has been properly selected, there is no reason why the patient should not get well, provided the ligature has not divided any of the arterial coats."

In 1895 was published the monograph of Professor Edmond Souchon, of our city, a most masterly and exhaustive treatise which has received uniform commendation. In it he gives a full account of all previous operations and formulates definite rules of procedure. So succinct, definite and valuable are the rules laid

down by him, that the operative methods he advises are generally followed. It should, however, be stated that no method advised by him is original, every one having been employed by earlier operators. But Dr. Souchon's work has given a remarkable impetus to the operation for ligature of large vessels. He insists on two points as of paramount importance for success, namely, two or more noncontiguous, absorbable ligatures and the non-rupture of the coats.

The adhesion of the coats may be effected in smaller vessels without difficulty, says Thomson (*British Medical Journal*, Vol. II, 1882), but in such a large vessel as the innominate there must be a certain amount of crumpling of the vessel within the ligature loop when that is drawn tight. Upon this circumstance Barwell observes: "It would seem that the tube, puckered and narrowed to a mere rift by the ligature, would afford an excellent surface for, and would soon get occluded by, blood-clotting."

The postmortem examination in Thomson's case showed this condition to be actually present. Although the ligature was drawn home, a chink still appeared to have been left, but that chink was closed by a firmly organized clot, which projected through it towards the carotid and subclavian arteries. These vessels were indeed closed by a clot which was throughout continuous with the large mass which occupied the cardiac portion of the innominate.

A protest against the principle of division of the vessel's coats, when tied in its continuity, was made by Charles Bell so late as 1842, and the opinion of modern surgeons has upheld him in that opinion. As to the necessity of the formation of a clot for the perfect closure of an artery, Spence's experiments (*Lectures on Surgery*) show that the presence of a coagulum within the vessel, filling up its canal for some distance, and ultimately becoming adherent to and incorporated with its parietes, was not essential to perfect obliteration. His experiments further showed that however common the presence of a clot, or however valuable as an accessory it might be when present, it was not essential in the process.

Recent experience shows the importance of applying two ligatures to the vessel to insure complete and permanent closure of its lumen. They should be placed about half an inch apart, if space will allow. The distal ligature is depended upon to permanently close the vessel, and the proximal one protects the first from the powerful concussion of the arterial current. In the present case, just as in Burrell's case, the proximal ligature cut its way through the arterial coats and was found inside the vessel, the lumen of which had been restored. The danger from hemorrhage in such cases is averted by the formation of a thick, fibrinous ring around the artery at the seat of ligature.

As to the question of the division of the innominate artery between two ligatures, I can do no better than quote Gray's explicit opinion: "It does not seem wise," says he, "to divide the innominate artery between the ligatures to relieve axis tension, as has been done with apparently good results in tying the carotid and other large vessels. The violence of the systolic impact, the strain upon the proximal ligature, and the tendency of that thread to cut through the arterial coats, the unreliable character of the proximal thrombus, the lack of the firm lateral support which is present in the neck, thigh, and other large arteries, the fact that the innominate artery is surrounded by loose, cellular tissue,

suspended, as it were, in soft, nonresisting structures, would all seem to militate against the practice of severing the artery for fear of secondary hemorrhage."

It must not be forgotten that successful ligation of the innominate artery is largely a matter of asepsis, and it is here that modern surgery should demonstrate its superiority. The surgeon, nowadays, does not wait expectantly for the separation and withdrawal of the ligature about the tenth day as formerly, but seals up the wound and trusts in his asepsis and technic.

The various materials which have been used for ligatures in ligation of very large vessels are as follows: Silk, hemp, catgut, ox aorta, kangaroo tendon, etc., in fact every variety of material has been employed. "It would seem," says Harte, "that a ligature composed of animal substance which would in time lend itself to the tissues and yet be sufficiently strong, would be most likely to meet with success; although there is always an element of uncertainty in the employment of such a ligature for fear that it may become absorbed too soon or its knot become insecure through the softening process of heat and moisture."

Burrell employed two flat, braided silk ligatures, passing one above the other about a half an inch apart. His object was to rest the artery by severing the vessel between them, thus avoiding the tracheal tug.

The ligature must be aseptic, and a silk ligature can be rendered more thoroughly aseptic than any other without injuring its strength.

The collateral circulation in these cases is established through the left carotid and vertebral arteries, the circle of Willis, the corresponding arteries of the right side, also through the thyroid arteries, the intercostals, especially the superior, the mammary, the profunda and princeps cervicis, and doubtless through many other smaller vessels of the arterial system.

It has been suggested by some surgeons, and I think it unquestionably safer that in such an operation as this, the common carotid and perhaps the vertebral ought to be ligatured at the same time, with the object of cutting off the recurrent circulation not only from contact with the seat of ligature on the innominate and preventing the formation of a clot, but from supplying the distal tumor. The carotid was so treated in Smyth's case. Thomson states that as a matter of fact the carotid has been frequently found closed when the innominate only was tied.

The failure of other methods than ligation for the treatment of aneurysms of the very large arteries has led surgeons to persist in the method offering the best results. After consideration of the uniform fatality of the operation by the proximal ligature, it would seem that Basedow's method of tying the carotid and subclavian arteries would offer a more promising method of procedure. In the only opportunity I have had of witnessing the application of this method the result was not encouraging. The case was Dr. Parham's, who, two days prior to my first operation on the present case, operated for a large aneurysm of the innominate artery, and syphilitic in origin. A catgut ligature was placed on the third portion of the subclavian artery and on the right common carotid near its bifurcation. The patient lived 20 days after the operation and finally died of suffocation by pressure on the trachea—a result probably due also to too much back-pressure upon the heart.

For the treatment of aneurysms various methods have been recommended, several of which have apparently been followed by good results, but the history has sel-

TABLE—SHOWING CASES IN WHICH THE INNOMINATE ARTERY WAS LIGATED FOR SECONDARY HEMORRHAGE.

NO.	OPERATOR.	DATE OF OPERATION.	SEX AND AGE.	CONDITION REQUIRING OPERATION.	ARTERIES LIGATED.	LIGATURE USED.	DATE OF HEMORRHAGE.	TIME OF DEATH.	CAUSE OF DEATH.	PLACE OF RECORD.	RECOVERIES AND REMARKS.
1	Huclin, Paris.	1842	M. 27	Secondary hemorrhage. Penetrating wound, injuring long thoracic artery.	Third portion of subclavian; then innominate, 9 days after.	Not mentioned.	None from innominate.	12 hours after operation.	Hemorrhage.	Lancet, 1842, Vol. 1, and Archives de Chirurgie Française et Éttrangère.	
2	Lynch.	1867	27	Secondary hemorrhage from gunshot wound of inferior carotid and vertebral arteries.	Innominate; common carotid had been tied a month previously.	Not mentioned.	12th day.	12th day.	Hemorrhage.	Quoted by Burrell, Boston Medical and Surgical Journal, 1895, Vol. 133.	
3	Partridge, S. B., Chicago.	1876	M.	Secondary hemorrhage from carotid aneurysm.	Innominate; 13 days previously, common carotid had been tied.	Not mentioned.	13th day from carotid.	1½ hours after second operation.	Shock.	Indian Annals of Medical Sciences, Vol. XIV, p. 22.	
4	Lewtas, J., Iowa.	1880	M. 20	Hemorrhage following traumatic subclavian aneurysm.	Innominate and carotid.	Catgut.				British Medical Journal, 1889, Vol. II, p. 332.	Recovery reported 43 days after operation.
5	Harte, R. H., Philadelphia.	1897	M. 26	Secondary hemorrhage from gunshot wound of neck (common carotid.)	Innominate; right subclavian and carotid.	Silk.	On day of second operation and 10 days previously.	A few hours after operation.	Hemorrhage.	Annals of Surgery, 1897, Vol. XVI, p. 489.	At last operation, right common carotid had been tied in two places.

TABLE—SHOWING CASES IN WHICH THE INNOMINATE ARTERY WAS LIGATED FOR SUBCLAVIAN ANEURYSM.

NO.	OPERATOR.	DATE OF OPERATION.	SEX AND AGE.	CONDITION REQUIRING OPERATION.	ARTERIES LOCATED.	LIGATURE USED.	DATE OF HEMORRHAGE, IF ANY.	TIME OF DEATH.	CAUSE OF DEATH.	PLACE OF RECORD.	RECOVERIES AND REMARKS.
1	Mott, V. New York.	1818	M. 37	Aneurysm of innominate, carotid and subclavian.	Innominate.	Silk.	23d day.	26th day.	Hemorrhage.	Medical Repository, N. Y., Vol. I, 1818.	Innominate artery was closed.
2	Græb, Berlin.	1822	M. 30	Aneurysm of right subclavian.	Innominate.	Not described.	A few days before death.	67th day.	Hemorrhage.	Med. and Phys. Jour., 1823, p. 475; Brit. Med. Jour., 1882, p. 728.	Aneurysm needle had partially transfixed artery, accounting for hemorrhage.

dom been followed up for a time sufficiently long to acquaint us with the ultimate results of the operation.

The much lauded gelatin-injection treatment, from which, after the favorable French accounts, so much was expected, has proved a failure in other countries. The latest device, however, which consists in the wiring of aneurysm followed by the passage of a mild electric current, has given excellent results. But a few weeks ago we listened with pleasure and interest to Dr. Matas' elaborate report of a case of abdominal aneurysm treated by this method. Stewart's pioneer achievements in this method of treatment have proved a source of encouragement to the profession throughout the country. He reports (*Brit. Med. Journal*, vol. ii, 1897) a case of a large innominate aneurysm completely cured by the employment of electrolysis through ten feet of snarled, coiled, fine gold wire introduced into the sac. The patient died from cerebral thrombosis three and a half years after the operation. Stewart says that the result of electrolysis through the introduced wire was very decided. Clot-formation, leading apparently to solidification of the sac, was early manifest. This method is worthy of further trial in the treatment of large aneurysms.

The operation proposed by Fergusson, amputation at the shoulder-joint, with ligation of the artery as close as possible to the sac, was performed five times with two recoveries (Souchon). It was done on the right side by Rose with partial success. Rose also tied the carotid and thus succeeded in saving the patient. Spencer (*Brit. Med. Journal*, 1889, p. 73) makes mention of two cases of subclavian aneurysm that were treated by amputation at the shoulder-joint. The first case was operated on by Holden, who removed the upper extremity for an aneurysm of the subclavian artery. Death on the thirty-seventh day from pleurisy and bronchitis resulted. The other case was Willett's. He tried to ligate the third portion of the subclavian artery for subclavian aneurysm and had to abandon the attempt owing to his inability to reach the proximal side of the aneurysm. The upper extremity was then amputated at the shoulder. Death followed.

As the postmortem examination in my case showed, no further operation would have been successful.

The cause of death after operation is either from sepsis, secondary hemorrhage, usually from the distal side of the ligature, or shock.

I have made a very full search into the literature of the subject and have succeeded in obtaining verifications of 34 cases, including my own case, in which the innominate artery has been tied for subclavian aneurysm. Twenty-nine were performed for aneurysms of the subclavian artery, generally involving the function of the common carotid and innominate arteries, and five times it was performed for trauma. Of these five, one was for hemorrhage from the subclavian (Lewtas), one from secondary hemorrhage following ligation of the subclavian (Hutin), three for secondary hemorrhage following ligation of the common carotid (Lynch, Partridge, and Harte).

According to Spencer (*Brit. Med. Journal*, vol. ii, 1889) subclavian aneurysm is about three and a half times more common on the right side than on the left, and on the right side about six times more frequent on the third portion than on the first. The spontaneous are six times more common than the traumatic.

Of the 34 cases just mentioned four are usually reported as recoveries. The first is Smyth's, of New Orleans, in 1864. In that instance, following the sug-

gestion of Mott, he ligated the common carotid artery also. This well-known case survived the operation, narrowly escaped the usually fatal result, lived ten years, then died from rupture of the reformed aneurysm, the result of reverse collateral circulation. The second case is Lewtas', of India, in 1889, reported cured at the end of 43 days. The third is Coppinger's, of Dublin, in 1893, who reported a recovery at the end of 42 days. If these last two cases are accepted as recoveries, a fourth might with justice be added to the list, that of Burrell, of Boston, in 1875. Burrell justly takes exception to the too early report of Lewtas' and Coppinger's cases when viewed in the light of his own case that lived 104 days and died of hypertrophy and dilation of the heart and general arterial sclerosis, and also of the case of Graefe, of Berlin, operated on in 1822, which died on the sixty-eighth day.

But a careful analysis of these four successful cases will show that not a single one has been a complete cure. Smyth's case came nearer being a positive and complete cure than any other. Still, his patient died of hemorrhage from the aneurysm ten years after the operation. The second and third cases had not been under observation sufficiently long to establish positive cure.*

Whether we think of the hopeless character of these subclavian aneurysms and their most painful course, we are led to believe that other surgeons will in the future devise some safer and more successful method of treatment. In the meantime we must depend on our present unreliable methods. And still such is my confidence in the method adopted in this case, that I am bold enough to assert, in conclusion, that under favorable circumstances the operation by ligature is in certain conditions justifiable and advisable, and that, with the improvements in the physical characteristics of the ligature and in the method of its application, also the modern aseptic methods, it may yet be followed by favorable results.

In the accompanying statistical table of the 29 ligations for subclavian aneurysms, which I append to this report, I have carefully eliminated those cases wherein secondary hemorrhage led to the ligation of the innominate and the unfinished operations. These I present in separate lists. In compiling these tables I am indebted to the statistics contained in the works of Thomson, Burrell, and Souchon. In the five years since the publication of Souchon's monograph, there have been recorded five operations for the ligature of the innominate artery, with as many deaths.

LIST OF UNFINISHED OPERATIONS.

1. Porter, W. H., 1831, Dublin, for subclavian aneurysm; ligature of innominate, abandoned on account of dilated vessel. (*Dublin Journal*, 1832, vol. i.)
2. Halbrunn, New York, 1839, for subclavian aneurysm, attempt to ligate abandoned on account of size of the innominate. (*Barrell, Boston Medical and Surgical Journal*, 1895, vol. 137.)
3. Key, London, 1841, for innominate aneurysm; abandoned operation on account of size of aneurysmal tumor. Death 23 days after operation. (*Dublin Quarterly Journal*, 1866, vol. 13.)
4. Passoto, Rio Janeiro, 1881, patient is a man 33 years of age, with hemorrhage from right ear. Ligature of common carotid. Hemorrhage. Extant ligature placed around innominate three weeks after carotid ligation but not tied, and removed after 5 days. (*Memorias do Instituto de Hygiene*, 1885, vol. 19.)
5. F. W. Parham, New Orleans, for cervical aneurysm, involving the innominate. Man, age, 48 years. The aneurysm was excised by removal of a part of the skin, but not ligated because the two blood vessels could not be tied. Death from shock 17 hours after operation. (*New Orleans Medical and Surgical Journal*, 1896.)

* In a personal letter of Dr. Alfred Willett to Dr. Coppinger, dated July 4, 1895, more than two years after the operation, the writer states that the patient had been in St. Bartholomew's Hospital because his nervous system seemed somewhat broken down, but he was quite free from any sign of his old aneurysm (Souchon).

BRANCHIAL CYSTS AND FISTULAE.*

By W. M. L. COPLIN, M.D.,

of Philadelphia

Professor of Pathology in the Jefferson Medical College

As a result of the complex developmental processes requisite to the formation of the organs arising in the neck segment of the embryo a multitude of malformations are rendered possible. The formation of the branchial arches and associated clefts or more properly furrows, and the fact that, at the bottom of the furrows, internally as well as externally, the epithelium of the entoderm and ectoderm becomes contiguous, considered with possible errors at the anterior median junction of the projected developing columns, such as failure of median coalescence, render it at once apparent that all sorts of malformations or arrests in development may result. Such more or less complete persistence into extrauterine life of conditions normally entirely fetal may be manifested by almost any degree of abnormality from fissure of the entire neck to trivial fistulae, or from absence of more or less of the esophagus, lung, or other structure normally derived from the foregut, to the persistence of fistulae (often of capillary dimension†), blind sacs or cyst accumulations due to external and internal closure of canals without coalescence of intermediate tracts. I shall not attempt to go into the developmental processes concerned in the formation of the branchial clefts, as such information is attainable in any of the current works on embryology.

Hunezowski² (1789) reported two cases of congenital cervical fistulae; Dzondi³ (1829) called them tracheal fistulae and Ascherson⁴ demonstrated their pharyngeal connection. Heusinger⁵ reported 2 cases and gave a table of cases, 46. In his inaugural thesis (Paris, 1877) and later, Cusset⁶ gives with considerable detail the result of his studies on the subject. Guzman's⁶ thesis in 1886, and Bland Sutton's⁷ work on tumors should also be consulted. Senn⁸ discusses branchial cysts under teratomata. Recently Frederick Shimanck⁹ reported cases of branchiogenic carcinoma and reviewed the literature of malignant disease, arising in these abnormal cavities.

With regard to the classification of branchial cysts much diversity of opinion is found. Fevrier¹⁰ speaks of median and lateral cysts. Depending upon their proximity to the surface the cysts are spoken of as superficial or deep. As it is not always possible to determine accurately from which cleft the cyst originated the proposition to base the classification upon the embryologic origin of the defect can be scarcely regarded as satisfactory. Less satisfactory probably is the attempt to subdivide these cysts according to the contents, as the latter must be materially influenced by the presence of inflammation, hemorrhage, and infection, as well as its source; similarly situated and genetically identical cysts may contain dissimilar materials.

Based, however, upon the hypothesis that such a classification is justifiable such cysts have been called atheromatous (branchial dermoids), mucous, serous, and hematocysts. As none of these cysts are primarily blood-cysts it is probable that the last-named subdivision is hardly justifiable. In Marsh's¹¹ case the cyst contained a gelatinous material.

It has been proposed to name these cysts according to their anatomic position in the adult. From this

point of view such cysts are called auricular or auditory, parotid, submaxillary, sublingual, pharyngeal, tracheal, etc. If carried to its legitimate conclusion such a classification would be scarcely consistent, as we would have substernal, sternocleidomastoid and other anatomic subdivisions that would endanger our losing sight of the embryologic origin. Although possessing many disadvantages the classification based upon the character of the cyst wall, taken in connection with the origin of the process, possesses many advantages. This would at once subdivide the entire group into two subgroups, one in which the wall showed to a varying degree the histologic characters of the skin and which would merit the name branchial dermoid, and the other in which the epithelial lining showed more or less striking resemblance to the mucosa lining the mouth, pharynx, or respiratory tract. Cysts of the latter type would be called mucous branchial cysts. While considering the subject of classification it is well to remember that the branchial cyst is but one type of a malformation that may be manifested by at least four pathologic possibilities: 1. Branchial fistulae, canals extending from the external surface to one of the mucomembranous tubes or cavities, such as the pharynx, larynx, etc. 2. Where the external opening has been closed a blind fistula, pouch or tract with its internal opening retained, results. 3. An external fistula in which the pharyngeal, laryngeal or other internal orifice has been closed while the external opening persists. 4. Cysts like that observed in the case reported in which both internal and external orifices have been obliterated, giving rise to a closed cavity the wall of which possesses an epithelial covering. In the experience of Trelat¹² fistulous openings are seven times as common as true cysts.

As already indicated the structure of the wall depends to a certain extent upon the type of tissue that it imitates. In branchial cysts of the dermoid type the wall does not differ from that found in other dermoids except from the almost constant presence of lymphoid elements in the extradermal layer. This lymphoid layer may be scanty, consisting of a few aggregations of lymphoid cells scattered here and there or such agminations of lymphoid tissue as to constitute distinct nodes. While it is true that other dermoids may occasionally possess more or less lymphoid tissue it is very rare to find such accumulated masses as are observed in the dermoids of the type at present under consideration. In the branchial cysts imitating the mucous membrane in the character of the cyst wall the condition is practically always that observed in the case here reported. In a small number of cases the lining has been composed of cylindrical epithelium, rarely of the tall variety, and only exceptionally ciliated. Where the epithelium has been subjected to considerable internal pressure it may be flattened, of a low columnar (cuboidal) type, or less frequently quite resembling squamous epithelium. In only exceptional instances is it simple, usually stratified, the number of layers not uniform in different areas of the same cyst wall and not infrequently showing marked morphologic peculiarities in different areas of the same lining. When stratified the genetic layer shows more or less tendency toward a distinctly columnar type. It is not probable that epithelium is ever absent, and the only reported case that I have been able to find in which it was sought and not found is that recorded by G. Broesike,¹³ but as the specimen was not studied in the fresh condition the

* Read before the Philadelphia Pathological Society, January 10, 1901.

† In one of Heusinger's cases a thick whisker could be passed into the opening.

absence of demonstrable epithelium is not surprising. The muscularis mucosa may be demonstrated with difficulty or it may be on the other hand quite conspicuous. Sometimes it is composed of a scattered layer of smooth muscle cells, abundant at points, irregularly scant in other areas, and rarely arranged as a continuous membrane. Sometimes this layer is in immediate apposition with a firm connective tissue stratum composed of fully formed fibrous tissue in which may be found numerous leukocytes, usually of the lymphoid type. This fibrous tissue merges into the loose connective tissue by which the cyst is attached to neighboring structures. Elastic fibers are present in the case reported. Adjacent to the fibrous tissue and, when it is absent, adjacent to the muscularis mucosa could be found a varying amount of lymphoid tissue. Sometimes this lymphoid tissue is in type and arrangement a more or less accurate reproduction of the structure of the tonsil. In other instances there is a lawless aggregation of lymphoid elements with a scant reticulum scattered along the submucosa at irregular intervals and in various sized aggregations.

A number of observers, Cusset,⁵ Roth,¹⁴ Monad and Dubar,¹⁵ and Guzman,⁶ have called attention to the presence of glands in the walls of branchial cysts. These glands may be of the serous or mucous type and show such aggregations as are found in the pharynx and esophagus of lower animals, and though less abundant in man; such glands may be distended by secretion, constituting true cysts in the primary cyst wall, or possess patulous ducts communicating with the general cyst cavity. Commonly the glands are not abundant and apparently may be absent or overlooked. The cyst wall may be uniform and quite smooth or it may be irregular, as in the case reported, of varying thickness depending upon the amount of lymphoid and fibrous tissues rather than upon the thickness of the epithelial layers.

Sometimes the cyst extends in finger-like projections between the muscles, great vessels, and nerves of the neck, or behind the hyoid bone, or downward behind the sternum or along the course of the auditory canal, rendering total ablation sometimes quite difficult, if not impossible. Sometimes the tumor projects into the pharynx or esophagus or passes posteriorly to that structure or between the esophagus and trachea or larynx, and while presenting superficially as a rather simple and readily accessible mass it may at operation present unexpected difficulties.

The communication of blind or open fistulae with the air-passages may give rise to air-sacs; those sacs possessing internal openings into the trachea may present the features of that rare condition variously termed aerial goiter, aerial bronchocele, tracheocele and hernia of the trachea. Stuart Eldridge¹⁶ reported one such case and collected the literature bearing upon the subject. I gather from a perusal of his paper that he believed it quite possible for the defect to be latent, a mere point of weakness, which, under unusual stress, became manifest.

With regard to the symptoms of this condition little need be said, as they suggest themselves. The external opening of fistulous tracts may be situated almost anywhere in the anterior portion of the neck, about the auditory canals, in the temple, in the neighborhood of the jaws, etc., but always anterior to the sternocleidomastoid muscles. The external opening is commonly marked by a discoid area of scar tissue or sometimes it

may be so inconspicuous as to escape superficial examination. Only rarely can the fistulous tract be followed by a probe. Fevrier¹⁰ reports the occurrence of severe reflex symptoms—pallor, palpitation of the heart—as a result of attempted exploration of a pharyngeal fistula. The discharge is usually clear mucus, but may be mistaken for salivary secretion from which it is easily differentiated by the usual chemical methods.

Where the fistula is complete and communicates with the esophagus or pharynx droplets of milk may escape during deglutition.⁷ The location of the external opening is rarely a guide to the extent and relations of the fistulous tract or sac. Stimulation of salivary secretion by citric acid or mastication usually stimulates the secretion from the sinus even when it does not communicate with the alimentary canal.

A. Section from thick portion of wall of branchial cyst. Tissue shown is richest in lymphoid tissue, and is without preservation of any of the original epithelial structure, and is freely infiltrated by connective tissue. B. Section of wall of branchial cyst at point where finger-like projection is extending toward the external opening. Layers shown are: a. Serous layer; b. Epithelial layer; c. The submucosa; d. The connective tissue layer. C. Section of wall of branchial cyst. Epithelial layer of cyst wall. b, b', b' connective tissue layer. c, c' lymphoid elements in cyst wall. At d' these lymphoid elements are aggregated in masses resembling the tonsil. In the center of the section a dilated gland duct is observed in the cyst wall. f. Irregularly dilated gland ducts. Tissue fixed in Heidenhain's solution, infiltrated with paraffin, stained with carmalum and cleared in cedar oil. (J. Mass. Journ. April, 1909, vol. 1, page 15, No. 2.)

When opening internally without an external opening the condition is commonly spoken of as a pouch or diverticulum (congenital);* when communicating with the esophagus it may fill during feeding or the internal opening may be so small as not to admit food. It may be evacuated by pressure, or the patient may find that by assuming a certain position the food does not enter the diverticulum.

* For description of cases of this type see No. 2, p. 15, loc. cit.

Like the fistulae the cysts are, in the neck, located anteriorly to the sternocleidomastoid, in the parotid or auricular region, in the neighborhood of the hyoid bone, or maxilla, in the interclavicular notch, or less commonly substernal, presenting at the last-named point.

The character of the contents has already been considered. The striking resemblance in some cases to pus or to the caseous contents of tuberculous lesions may mislead the operator; as indicated in the report which follows it would seem that the character of the cells found in the fluid should at once clear up the diagnosis.

With regard to the age at which the lesions manifest themselves it may be said that the fistulae are usually present at birth. They may appear later as a result of opening of pouches or cysts or incomplete extirpation. Like dermoids of other kinds the cyst may escape detection until adult life or later. In Cussett's⁵ cases the patients were 10, 15, 21, 22, and 26 years of age. In the case reported the specimen was sent to the laboratory by Professor W. W. Keen, to whom I am indebted for the following clinical notes:

C. E., age 36, first consulted me November 6, 1899, at the instance of Dr. C. W. Richardson, of Washington, D. C. His father and mother are living, and in good health. Of his grandparents he knows nothing, except that his paternal grandmother died of old age at about 85; he believes that all of his family were healthy. One sister died of diphtheria. Three years ago he noticed a lump on the lower jaw on the left side, no pain, no inflammation, in fact no symptoms whatever. Its size was that of a peach stone until about 8 months ago, when it began to grow quite rapidly. There have been, however, no symptoms connected with it, excepting a slight, dull pain about the side of his face, and he thinks it has affected his head, as he has become very forgetful. He has lost 28 pounds in the last 6 months, weighing at present 175 pounds, but this may be due to other causes. On examination I found a soft, almost fluctuating tumor, 10 by 6 cm., presenting the features of a lipoma.

Operation, November 15. An incision was made parallel with the jaw, and after cutting down through the m. laryngoid the back of the tumor was reached. This proved not to be a fatty, but a cystic tumor. The fluid looked very much like pus. My judgment was that it was a cold abscess either in the connective tissue or in a very much enlarged and softened gland. I was able to dissect the whole of it out, exposing at the bottom of the wound the great vessels of the neck. I very carefully washed the wound out with salt solution, and then closed it with drainage. He made a perfectly smooth recovery, highest temperature being 100° F.

Pathologic Report—Specimen, cystic tumor of neck. Specimen consists of an almost empty, flaccid sac, measuring 7 cm. in its longest diameter. It is oval or slightly pear-shaped. It contains a pinkish-white opaque fluid that resembles pus. The external wall of the cyst is covered by an aborescent outline of bloodvessels. The lines of dissection from the adjacent tissues are recognizable. By reason of perforations in its wall it was impossible to refill the cavity and determine its capacity. Approximately one-half the cyst wall is thin (1 to 2 mm.) perfectly transparent, and containing a few bloodvessels. The remainder of the wall is thicker, but quite irregular in thickness. Its maximum thickness occurs in slightly bossed elevations approaching 1 cm. The average thickness of the wall does not exceed .25 cm. It is irregularly studded by greyish translucent elevations. The largest of these elevations are palpable, resembling tubercles. At one point in the thickened wall is a yellowish mass apparently caseous. This mass is ovoid, .7 cm. by .5 cm. in diameter. It is situated within the thickened wall and covered by a thin layer of tissue. At other points the cyst-wall is traversed by thin septa, dividing it into irregular depressions. In a general way the color is pinkish with areas of what appears to be hemorrhage, some of which are purplish. At some points the wall is fibrous and very dense, in other areas it is soft and yielding. Weight 17 gms.

Fluid contents of the cyst: The quantity is insufficient to determine the specific gravity. The cells vary in size and contour in the size of the nucleus and in the quantity of perinuclear protoplasm. The best picture of these cells is obtained in spreads, dried, fixed by heat, and stained in hematoxylin and eosin, toluidin-blue and eosin, and Unna's polychrome methylene-blue.

1. The most abundant cell observed in such preparations is of relatively large structure, varying in size from 12 or 15 μ to 35 or 40 μ . In shape these cells are irregularly oval, a few are round or discoid, while by far the large part are irregularly polyhedral. The majority of these cells are mononuclear; occasionally, a cell is to be found containing two nuclei, and in very rare instances three distinct nuclei can be recognized. Some of the nuclei, indeed one may say the majority, are in a fair state of preservation. Nuclear fragmentation, fissuring, vacuolization and polychrome reactions are recognized. In some of the cells a distinct nuclear structure is no longer to be recognized. In others the nuclear remains are but faintly tinted, constituting irregular shadows in the cellular protoplasm, while in still others the chromatin is fragmented into irregularly outlined granules which stain unevenly. In many of the cells the nuclear margins are indistinct. The perinuclear protoplasm is, for the most part, finely granular, and takes the acid stain with varying degrees of intensity. Its volume varies within wide limits: the different-sized cells owe their differences in size to variations in the quantity of protoplasm rather than to any variation in size of the nucleus, which is rather uniform. There are apparently free nuclei which probably belong to these cells as indicated by the irregular, ragged rim of protoplasm which stains unevenly and often but slightly. The protoplasm is vacuolated in many of the cells, the vacuoles varying in size from 1 or 2 μ to 7 or 8 μ . In some of the cells of this group, the margin is fairly regular and clearly defined. In others, the margin is ragged but sharply outlined, while in still others the protoplasm fades off, and is gradually lost without any sharply outlined limit.

2. An occasional finely granular oxyphile leukocyte can be recognized, although the number of such cells is remarkably small.

3. Occasionally one finds a cell morphologically and tintorially like a mononuclear leukocyte. These cells, however, are not abundant. There are a few masses of cells, in which distinct differentiation cannot be made out, and within these might be included other cells than those described. A few erythrocytes are present.

A count of a thousand cells in spreads made from the fluid gives the following result in percentages:

1. The large cells resembling the squamous epithelial cells described above, 93.7%.
2. Finely granular oxyphile leukocytes (polymorphonuclear leukocytes), 1.8%.
3. Erythrocytes, .5%.
4. Uninuclear leukocytes and unidentified cells, 4%.

Portions of the cyst wall at various points were fixed in Heidenhain's solution, infiltrated with paraffin, sectioned, and sections stained with carmalum alone and with picric acid, hematoxylin alone and with eosin, Unna's acid orcein, Unna's polychrome methylene-blue, toluidin-blue alone and with eosin, toluidin blue with differentiation in styron and glycerin-ether, and by Gram's method, and for tubercle bacilli with carbolfuchsin.

For convenience in description, and for the sake of

brevity, the sections from the following areas will be considered :

A. Sections from the thin part of the wall. B. Sections from the thicker areas.

A. The best sections from this part of the wall are in the neighborhood of areas where the thin wall is suddenly or gradually converted into a thick wall by changes which will be mentioned later.

The inner aspect of the wall is lined by large polygonal cells, evidently epithelial. Toward the free margin the cell outlines are not distinct, the nuclear stain is not strong, and vacuoles are abundant in the perinuclear protoplasm, which, under a very high power, is slightly granular; although it is impossible to give accurately the thickness of this layer (which varies) as it merges gradually with the cells below, it may be stated that it approximates two or three of the cell-layers. Just under this layer the irregular polygonal cells become more sharply defined both in outline and stain reaction. Toward the upper layer already described, the nuclei are less distinct, becoming more and more clearly defined, and stained with greater intensity as we approach the subepithelial layer. The germinal or basement layer of epithelium is irregularly columnar, with deeply stained nuclei, in some of which changes suggestive of karyokinesis are to be recognized. From this layer passing upward can be recognized the gradual transition from the irregularly columnar form to the more or less flattened, irregular, and poorly stained cells already described as present upon the free surface.

As indicated by the above description the epithelium of the wall cannot be divided into distinct layers, although there is the suggestion of a stratum corneum and stratum Malpighii. A distinct muscularis cannot be recognized in sections stained in the usual nuclear dyes, although here and there a few long spindle-shaped cells with rodlike nuclei are to be recognized. In sections stained in acid orcein a delicate basement membrane can be recognized at nearly all points; this structure sends trabeculae downward in many areas, penetrating the lymphoid tissue below. While the stratum germinativum is slightly irregular one cannot say that there is anything more than a mere suggestion of papillae. Immediately under the epithelial layer described one finds nearly the whole length of the section a slightly irregular layer of lymphoid tissue. The reticulum varies in quantity, being at some points rather abundant and at other areas scanty. It is not rich in blood-vessels, particularly toward the epithelial surface; as we approach the outer limits more vessels are to be recognized. The cells occupying the reticular spaces correspond for the most part with the usual type of lymphoid cell, and scarcely merit further description. A few finely granular oxyphile leukocytes are present, although there is certainly no excess of these elements. At points the outer wall, or I might better say outer limit of the wall, is formed by lymphoid tissue. In other areas it is formed by masses of fibrillated connective tissue comparatively rich in bloodvessels and containing a few unstriped muscle-fibers. The roughened and irregular free margin at this point is, of course, due to its dissection from adjacent tissue. I have not been able to demonstrate the presence of striped muscle-fibers in this area.

B. *Sections from Thicker Areas in the Wall.*—As the increased thickness of the wall in different areas is due to different causes it would be necessary to consider these areas separately.

1. Areas in which the thickening is due to a thicker wall of lymphoid tissue. The epithelial covering in these areas deserves no special description, as it varies little if at all from the epithelial layer seen in the thinner wall. Partly as a result of its increased thickening and possibly from other causes, the cellular elements usually present on the mucous surface can be more readily recognized, although, as is usual under such circumstances, differentiation into layers is not clear. Cross-sections of flattened cells, such as those already described as present in the fluid contents of the cyst, with flattening, or slight elongation of their nuclei, are to be recognized. There is the same gradual transition from the irregularly columnar germinal layer to the flattened surface layer already described. In some of the thicker areas the lymphoid tissue is more abundant and the reticulum scanty. In other areas the reticulum is more abundant, with a suggestion of proliferative change and corresponding reduction in the richness of lymphoid cells. Distinct arrangement of cells such as compose adenoid follicles of a lymphatic gland can be recognized, and occasionally there is a suggestion of medullary cords, although demonstration of these structures is not complete. External to the lymphoid areas just described there is the same area of fibrillated tissue containing a few long, spindle-shaped cells with rodlike nuclei. A further study of these lymphoid masses reveals the presence of necrotic spots. Such points embrace only a few cells. Just beneath the germinal layer in some of the sections there is a lymphoid infiltration of the connective tissue not associated, however, with the presence of finely granular oxyphile leukocytes. These bodies are not abundant at any point in the section.

2. Areas in which the increased thickening of the wall is due to the presence of cysts. The epithelial covering in these areas merits no further consideration than that already given. Only one of these cysts will be described. In designating this distinctly as an additional cyst, the possibility of its communicating at some points with the larger cysts cannot be overlooked, although such communication cannot be demonstrated even in serial sections. The wall of this cyst is formed by an inner zone of squamous epithelium which has been detached or has disappeared from some areas. It shows the same general appearance as that already given for the epithelial lining of the larger cyst. At one point the two cavities are separated by a thin wall less than 1 mm. in thickness composed of two epithelial surfaces between which is a small quantity of fibrillated tissue rich at points in lymphoid cells.

Macroscopically on section this cyst possesses a diameter of .3 cm. and corresponds with what was mentioned in the gross description as a distinctly yellowish mass measuring .7 by .5 cm. The difference between the diameter in the gross specimen and the section is probably to be attributed to shrinking and the removal of fluid from the interior of the cyst or to the section not passing through the greatest diameter. The cyst contents as examined in the fixed and infiltrated preparation are usually composed of fine, intensely acidophilic granules resembling in many respects the detritus in caseous areas. That it is not caseous in the true sense is shown by the fact that it contains large squamous epithelial cells such as have been identified in the fluid from the larger cyst. Most of these cells have lost their characteristic stain reaction, selecting only the acid dye and therefore possessing indistinct, irregularly defined nuclei and cell outlines.

The contents as here studied must be considered to be the product of degenerative changes in the epithelium which has been cast off into the cyst cavity. Three smaller cysts identical in all their essentials with that just described have been found, and it is reasonable to infer that the many small whitish or greyish, translucent elevations mentioned in the gross description were probably, or at least some of them, cysts resembling the one just described.

3. Sections from other areas in the cyst wall show evidences of chronic inflammation manifested by a lymphoid and plasma cell infiltration with the production of fibroblasts, and in some areas cicatricial tissue. At a few points the mucosa shows distinct papillae. They are, however, not abundant. Occasionally there is a distinct fold resembling the irregularities or rugae observed in mucosae surrounding cavities whose walls possess considerable distensibility. Transverse section of the overhanging rugae gives the appearance, at times, of superficial gland-like projections. Serial sections, however, show clearly that these are folds. In other areas distinct glands are demonstrable and it is evident that the cysts already described have resulted from distention of gland acini, or ducts, or both.

Bacteriology.—Cultures were not obtained from the cyst contents. Spreads and sections show the presence of a few cocci in the cyst contents and in the wall; these cocci stain by Gram's method, are apparently staphylococci, few in number, and the absence of cellular infiltration as well as the scant necrosis would indicate that the infection, if such existed at the time of extirpation, is inconsequential.

Diagnosis and Remarks.—There can be no doubt of the branchial origin of this cyst. The character of the epithelial covering, its arrangement, the morphology of its cells, the structure of the submucosa, the presence of cysts in the wall, the abundant lymphoid tissue and the cyst contents all point to the branchial origin. From a practical view the character of the cells found in the fluid contained within the cyst offers important diagnostic aid. The small number of leukocytes of the type usually found in pus and the presence of large mononuclear cells rich in perinuclear protoplasm, and the absence of necrotic material should be in the future of value in diagnosis. In cysts of endothelial origin, similarly located, it is not likely that exfoliated cells would ever present the morphologic and tinctorial characters recognized in the case reported. Endothelial cysts possessing richly cellular fluid contents would, no doubt, owe their cellular elements to the presence of migrated leukocytes and exfoliated endothelium, in which case no such a cell count as that reported would be found. It would therefore appear to the writer that an examination of the fluid that came from such a cyst, taken in consideration with its location and clinical history should make the diagnosis less difficult than it at first appears.

With regard to the treatment little need be said; total ablation, where possible, is the only commendable plan. Pockets that cannot be excised may be cauterized. Poncet¹² used chlorid of zinc but does not give the strength of the solution used; tincture of iodine, carbolic acid or the actual cautery may be used. All surgeons are agreed that the use of irritants and escharotics, either by injection or application with a swab, is untrustworthy.

METHOD FOR RAPID ELIMINATION OF THE GONOCOCCUS.*

BY FOLLEN CABOT, JR., M.D.,
of New York.

In the treatment of acute anterior gonorrhea we should devote our efforts to the avoidance of complications and to the rapid elimination of the gonococcus, aiming in this way to shorten the course of the disease. Much has been done and written upon the various methods of treatment of acute anterior urethritis with the object of shortening the course of the disease. Nearly all the methods, however, which have been employed have either entirely overlooked the first condition I have mentioned—and directly or indirectly produced complications by a too violent form of treatment—or else by the use of too weak solutions or a faulty technic have failed to overcome the resistance of this very obstinate microorganism.

In this paper I shall refer entirely to the treatment of gonorrhea in its incipient stage; that is to say, within 24 to 36 hours from the time any moisture has appeared at the meatus.

In a series of 30 cases in which this treatment was carried out, $\frac{7}{8}$ of the patients recovered after 8 to 10 days; in the remaining $\frac{1}{8}$ no complications ensued, but the treatment did not markedly shorten the course of the disease. Before describing the method which I have used successfully I will refer to some of the other methods of treatment of acute anterior gonorrhea. By one method, at the earliest sign of discharge or local manifestation, the front urethra is washed out with a 10 : 15,000 volume peroxid solution, and then, by the aid of an endoscope or frame speculum, the anterior urethra for fully an inch beyond the diseased area is wiped out with a silver-nitrate solution—5 to 10%—applied on a cotton swab; this procedure to be repeated, if necessary, in 48 hours. In some cases this treatment has been successful, but occasionally the reaction following the use of strongly irritating solutions and manipulation in making the applications led to complications; while in others, the course of the disease was much aggravated and prolonged. In other words, the treatment was much too violent for the sensitive mucous membrane of the urethra. This method of treatment I believe has been, at the present time, largely discarded.

The advocates of irrigating the front urethra in the early stage of gonorrhea claim that much can be accomplished by large volumes of hot medicated solutions. One method of using these solutions is the so-called Janet method; that is, washing out the whole urethra and bladder by overcoming the resistance of the shut-off muscle. This method I believe to be too energetic in the acute stage, and when the front urethra is alone in-

* Read before the Harvard Medical Society, November 24, 1900.

volved, unnecessarily thorough; if we had to deal with an urethral tract alone it might do, but considering that the genital organs are intimately connected with the urethra this treatment is liable to produce complications and is, therefore, in my opinion in acute gonorrhea unsatisfactory and dangerous.

Another method of irrigating the front urethra is by the double-flow nozzle introduced at the meatus and attached to a fountain syringe. This has been used to a considerable extent, the outlet opening being larger than the inlet to avoid any overdilatation of the urethra. It has been demonstrated, however, that the urethra, after being filled with the solution in this manner, simply remains distended, the fluid entering from the nozzle immediately flowing out without producing any general change in the body of the fluid within the urethra. This method is little better in my opinion than the time-honored one of filling the urethra with a solution from a hand-syringe, allowing it to remain in contact with the urethral membrane a few minutes and then repeating the operation.

Still another method by which irrigation has been used is by the aid of a soft rubber catheter passed a few inches into the urethra and the fluid from a fountain-syringe allowed to flow back over the canal from the eye of the catheter. In this way the whole urethra is bathed by a continuous flow of the solution. I believe this to be the best of the three methods just described for washing out the anterior urethra. If not introduced too far and carefully used it is devoid of danger. I believe, however, that one objection to these methods is that some of the secretion remains in contact with the urethra, thus preventing the solution coming in contact with the underlying gonococci. We must, of course, reach these deep microorganisms in order to prevent their growth.

The method I have used, and shall now describe, is a compromise between the endoscope and silver nitrate abortive treatment and plain irrigation. During the past 4 years I have used several preparations of the silver salts which I have found to be much more satisfactory and less irritating than silver nitrate; in fact, I believe some of them to be of much more value than other antiseptics in the treatment of the earliest stage of gonorrhea. I have used argonin, protargol, and largin. Argonin has been the one chiefly employed by me. In order to test the comparative antiseptic powers of argonin and protargol I tested these salts with pure cultures of the streptococcus and Klebs-Löffler bacillus, the results of which tests are given in the following tables:

STREPTOCOCCUS.

Argonin . . .	1% solution; 10 minutes exposure.	growth in 24 hours.
Protargol . . .	5% " " " "	no growth in 24 hours.
Protargol . . .	1% " " " "	no growth in 24 hours.
Protargol . . .	5% " " " "	no growth in 24 hours.

DIPHTHERIA BACILLUS.

Argonin . . .	1% solution; 10 minutes exposure.	no growth in 24 hours.
Protargol . . .	1% " " " "	no growth in 24 hours.

It will be seen from this table that argonin and protargol seem to have about the same antiseptic effect. I also made some tests with argentamin and other silver salts, but my results are insufficient for tabulation. I did not test the effect of argonin and protargol with the gonococcus in my bacteriologic experiments because I believe the gonococcus, which grows with difficulty in artificial media, to be much more easily destroyed than when in the human body. Such ex-

periments have been made, but I am of the opinion that they are not of much value. None of the animals available for bacteriologic work can be infected with the gonococcus. This statement is borne out by the majority of well-known investigators. There have been a few isolated instances where a gonorrheal infection of animals has been reported, as Finger's case of gonorrheal involvement of the knee-joint of a dog, and a few cases of peritoneal infection in mice. We must, however, accept the fact that animals are of no practical value in bacteriologic experiments with the gonococcus, so that artificial media and animals are of little aid in testing the effect of drugs on this microorganism. We must, therefore, draw our conclusions from the tests of various drugs on this microorganism in the human being. I have had much less experience with protargol, which contains 8.2% of silver, than with argonin, which contains 4.2%; silver nitrate, containing 6.35%, occupies a middle position between the two first-named preparations in its proportion of the basic salt. Both argonin and protargol are freely soluble in water. Argonin should be freshly prepared for each treatment. Protargol keeps better in solution than argonin. I have found argonin to be nonirritating.

I shall give the results obtained by the use of argonin within 12 or 36 hours after the first signs of local disturbance, as shown by slight moisture at the meatus, feeling of warmth in the end of the penis and slight burning on urination. Used later—that is, after the gonococci have buried themselves deeply in the mucous membrane of the urethra—the treatment I advise would be of little advantage. The case must be one of acute anterior urethritis with no old, deep trouble. This condition must be determined by an examination of the urine and of the rectum as well as by careful consideration of the past and present history of the patient.

I first take a specimen of the discharge for microscopic examination, then the patient passes urine, after which the urethra is washed out with hot water; I then, twice a day, introduce a 10% solution of argonin freshly made; this is introduced by a Ultzman's deep injection syringe or, better still, by a rubber bulb holding about 6 drams. This bulb should have a rubber tip about 2 inches long; the bulbs are sold under the name of ulcer syringes. The solution is introduced hot and is kept in the front urethra by pressing the lips of the meatus together as the point of the bulb is withdrawn. Then I make an application with an applicator tightly wrapped with absorbent cotton, of 10% argonin solution, introduced into the urethra while the solution previously introduced is allowed to gradually flow out. It is much easier to introduce the applicator while there is some fluid in the urethra. The cotton swab should be applied gently to all parts of the anterior urethra for two 2 or 3 inches and then withdrawn. The solution remaining in the urethra is then allowed to escape and the operation is repeated, not using the applicator if the patient complains of much pain. In some cases a gentle kneading of the urethra while the solution is in place is of advantage.

I do not believe in using cocain, as a rule, to deaden the pain, because it interferes with our power of gauging the patient's condition by his natural sensations. Everything must be done very gently and slowly. The solution must be kept in 5 or 10 minutes. The first two or three treatments will usually show what the

case is going to do; if all is going well, the disease instead of progressing in the usual manner remains stationary for 2 or 3 days and gradually subsides. This treatment should be given by the physician himself. Internally, citrate of potash may be given to render the urine bland. The patient is directed to soak the penis in hot water three times daily; the general condition of his health, the use of alcohol, etc., regulated. The patient should be kept as quiet as possible.

If the progress is favorable the strength of the solution is gradually increased and may be used as strong as 30%. In addition, at the end of two or three days, if everything is going favorably, I advise the patient to use an astringent injection composed of lead acetate, tannic acid, zinc sulfate, copper sulfate, of each 2 grains, in tablets. One of these tablets is placed in 4 to 8 ounces of water and used by the patient after each urination. Of course this is in addition to the argonin applications.

The personal equation comes into this treatment as into many others; on this account dispensary patients have not been as satisfactory as private cases. I examine for the gonococcus every other day. I expect, in satisfactory cases, to see improvement in three to four days; disappearance of the gonococcus on the sixth to seventh day, and disappearance of the discharge on the eighth to tenth day. The treatment should be continued for a week after the gonococci and discharge have disappeared. Of course the strength of the solution and the amount of treatment have to be changed with the condition of the patient. I will here give the result of the treatment in a case which is typical of several others in which I used this method.

CASE 1.—Referred to me by the courtesy of Dr. Duel. July 26, H. W. C., aged 32 years, complains of discharge of one day, no other symptoms except slight burning at the meatus. Had clap a year ago, which recovered after 2 weeks. Examination shows reddened meatus, first urine cloudy, second perfectly clear, discharge mucopurulent and fairly abundant. Deep parts by rectal examination normal. Specimen taken for examination. Gonococci found. Argonin 10% solution used on the 26th, at night; 27th twice; 28 h twice; his condition remained practically the same. No urgency or frequency of urination; slight burning of the urethra on urination; slight pain over left groin not increasing; general condition very satisfactory. July 28 introduced swab soaked in argonin solution 2 inches. Some slight erection in early A.M. 30th, another specimen taken for examination; gonococci fewer; urine shows less pus, few particles from front urethra. July 31st: 30% solution. Reddening and discharge much less; burning subsided; few erections now. August 1st: Discharge very thin, no gonococci in specimen, discharge only seen on pressure. Discharge disappeared on the 2d of August; on the 8th was still absent. Injection, of the formula given above, has been used in the last few days in addition to the argonin treatment. On August 2d, argonin injections reduced to one a day which was continued up to the 8th when the patient was discharged cured and has remained well. In this patient it will be seen that there was no discharge after the seventh day, the gonococci disappearing at the end of 6 days. The patient complained of little discomfort on the application of the swab with argonin.

In conclusion I will add—

1. That this method of treating incipient clap I believe is devoid of danger.

2. All the cases which have been satisfactory, as far as traced, have shown permanent results, there being no return later from deep lesions produced by the treatment, as is sometimes seen after the use of irrigation which has affected the genital organs.

3. Solutions must be freshly prepared each time and must be used hot, temperature of 110–120° F.

4. Unless the patient is prepared to give himself up completely to the physician's directions in all particulars there is no use in attempting to make a rapid cure of his case by this method.

RETARDATION OF GROWTH AS A CAUSE OF SHORTENING AFTER COXITIS.*

By HENRY LING TAYLOR, M.D.,

of New York

THE muscular wasting, so constant in the early stage of hip disease, appears to be hastened and increased by immobilization, compression and suspension of the affected limb. After months or years of pathological or mechanical interference with function the limb is finally much shrunken, not only in its muscular elements, but in all its tissues, including the bones, whose growth has not kept pace with that of the well limb either in extent or structure; they are finally smaller, shorter, and more brittle.

While the wasted muscles always seem capable of development after the subsidence of inflammation, within the limits imposed by joint-function, one cannot fail to be struck by the superficial resemblance between the shrunken appearance and bluish, clammy, surface of many of these bandaged and restricted limbs, and the atrophied limbs following infantile paralysis. This similarity extends in a remarkable degree to the retardation in growth, both longitudinal and circumferential, of the long bones of the affected member.

My attention was somewhat forcibly called to the importance of retarded growth after coxitis by the case of a boy of 15, who returned in 1891 after several years' absence; during the last two he had not worn any apparatus and had remained free from disease. He had grown rapidly and was in excellent health, but complained that his leg had grown shorter. On measuring the lower limbs, it was found to my surprise and chagrin that the shortening had increased from a trifle over 1 in. in 1887 to 4½ in. four years later. This led to separate measurements of the femurs and tibias, which disclosed a shortening of 2 in. in the femur and of 1½ in. in the tibia of the affected side. The remainder of the shortening was doubtless due to upward displacement of the femur, but here was over 2½ in. loss of growth in 4 years.

This incident made a deep impression and led to comparative measurements from time to time of the long bones of the limbs after coxitis, and occasionally after other affections. It soon became evident that differences of 1 in. in the length of the tibia and of ½ in. or more in the foot in old cases of coxitis were not at all uncommon. Within the last few months these measurements have been repeated in a series of cases of coxitis, and also in other disabling affections of one limb, to see if any generalization was warranted. Since the principal object of the investigation was to ascertain the length of the shaft of the long bones on the two sides, the femur was measured from the tip of the trochanter to the knee in the hip cases, to eliminate erosion, displacement and bending of the neck, which do not directly concern this study. Measurements of the length

* Read at the meeting of the American Orthopedic Association, Washington, May, 1900.

of the tibia, of the length of the foot, and of the breadth of the patella were also taken.

The results in 37 cases of coxitis may be seen in the table, which is divided into 3 sections according to the duration of the disease; the approximate averages are given for each group.

The results may be briefly summarized as follows:

Femur.—In 23 cases the shaft of the femur of the affected side was from $\frac{1}{4}$ to $2\frac{1}{2}$ in. shorter than that of the well side. In 9 cases there was no demonstrable difference, and in 1 case the femur was about $\frac{1}{4}$ in. longer.

always smaller and narrower; in many cases its bulk seemed to be less than half that of the well side. Twenty-six cases showed a difference of from $\frac{1}{8}$ to $\frac{1}{2}$ in. in transverse diameter, usually about $\frac{1}{4}$ in. In one measured case only was no difference found; this patient had walked freely and had never worn a brace.

Foot.—In 31 cases the foot was from $\frac{1}{2}$ to 1 in. shorter, and often distinctly smaller in other dimensions. In 5 cases no difference in length was noted.

If the cases are divided into 3 groups according to

— Denotes that the measurements on the two sides were equal.
Where there is a blank in the table, no measurement was recorded.

The shaft of the affected femur was often very much thinner to palpation, and the condyle much narrower and smaller. In 4 cases the femur was not measured.

Tibia.—In 35 cases the tibia was from $\frac{1}{8}$ to $2\frac{1}{2}$ in. shorter on the affected side; in 2 cases there was no difference. In 20 cases the shortening of the tibia exceeded that of the femur; in 7 cases the two were equal, and in 6 the shortening of the femur was the greater.

Fibula.—In a number of cases in which the fibula was measured, it showed about the same amount of shortening as the tibia.

Patella.—The patella of the affected side was nearly

the length of time which had elapsed from the beginning of the disease to the date of the last measurement the total shortening, as well as the shortening of the individual long bones, and of the foot, and the narrowing of the patella is found to increase progressively with the duration of the lameness. In some instances cases of long standing, which have had but little mechanical treatment, show less shortening, though there might be deformity and relapse, than cases of equal duration where mechanical treatment had been prolonged. After forcible correction of the deformity retardation of growth was exaggerated, though the cases are too few to generalize. In some cases retardation was much

above the average and in others much below, from unknown causes.

Infantile Paralysis.—In the third group of hip cases with an average age of 15 and an average duration of lameness of 11 years, the average bone shortening was slightly under $\frac{7}{8}$ in. in the femur and slightly under 1 in. in the tibia, or about $1\frac{3}{4}$ in. total. This group may be compared with a group of 10 cases of unilateral infantile paralysis with an average age of 13, and an average duration of lameness of 11 years, where the average shortening was about $1\frac{3}{4}$ in. and in no case over $2\frac{1}{2}$ in.

While the condition of the muscles in the atrophied legs after poliomyelitis is pathologically different, the fact that the longitudinal growth of bones seems to be no more retarded after paralysis than after coxitis, and that in both the affected limb is used very imperfectly, if at all, in support and locomotion, suggests that interference with the normal function of the limb may be an important factor in the retardation of skeletal growth. This inference is strengthened by the consideration that just as we may produce a partial paresis of the circulation by bandaging and suspending a limb, so we may cause such a condition to disappear in certain paralytic cases by bringing a useless limb into action.

Infantile Hemiplegia.—Many cases of infantile hemiplegia of long standing show a certain retardation of growth of the long bones of the affected side, though usually less than in poliomyelitis. (It is to be noted that the leg is used more in walking than in infantile paralysis.)

Congenital Dislocation of the Hip.—In 10 cases of unilateral congenital dislocation of the hip from 4 to 13 years of age the total shortening varied from $\frac{1}{2}$ to $2\frac{1}{2}$ in., but the femur was shorter ($\frac{1}{4}$ in.) in only one case, and the tibia ($\frac{1}{8}$ to $\frac{1}{2}$ in.) in 5. The foot was $\frac{1}{2}$ to $\frac{5}{8}$ in. shorter in the older cases, and the patella was slightly narrower in 6 cases. Here also we are to note that locomotion is constantly practised.

Hip Excision.—One case of excision of the head of the femur, at 2 years, showed no difference in any of the bone lengths at 5 years, though there was upward displacement of 1 in. It is my impression, however, that the considerable shortening after hip excision in children will be found to be partly due to retarded growth, after as well as before the operation. After knee-excision in children this shortening has been shown to be a progressive and most serious factor, owing as has been supposed to interference with the epiphyses.

Fracture of Neck of Femur and Coxa Vara.—No opportunity for measuring cases of fractured neck of the femur in children has recently presented itself. Dr. Whitman reports increasing shortening, which he attributes to change in the angle of the neck. It is possible that these cases and those of coxa vara occurring in the period of rapid growth may show some retardation on the affected side, but since the limb gets a fair amount of use, the retardation, as in the congenital hip dislocations, would probably be small and occasional only.

Osteitis of the Knee.—Of 9 cases measured, aged from $3\frac{1}{2}$ to 33, 6 had a duration of lameness under 5 years. All these showed lengthening of the affected limb, ranging from $\frac{1}{8}$ to $\frac{7}{8}$ in. The 3 older cases showed shortening from 1 to $2\frac{1}{2}$ in. In the first group the femur was longer in 4 from $\frac{1}{4}$ to $\frac{3}{4}$ in. The tibia was longer in 2, equal in 2, and shorter in 2. In the second

group the tibia was from $\frac{1}{2}$ to $2\frac{3}{4}$ in. shorter. In 7 cases the affected foot was shorter from $\frac{1}{8}$ to $1\frac{1}{2}$ in., and in all, the affected patella was from $\frac{1}{8}$ to $\frac{5}{8}$ in. narrower.

Here the proximity of the inflammation to the principal epiphysis for growth modifies the result. There is for a time acceleration of growth in length near the focus, but this goes hand in hand with retarded growth of the patella, and foot, and of the leg bone, unaffected by the irritation. The primary acceleration is followed by a later retardation from disuse, which usually more than counterbalances it.

Congenital Defects of One Lower Limb.—The type of congenital defect of a limb, characterized by imperfectly developed or absent long bones, especially of the fibula, and certain bones of the fibular side of the foot, shows a progressive retardation of growth. Here the tibia or femur, or both, may be the fraction of an inch shorter in early infancy, but the limb is little, if at all serviceable for locomotion, and falls behind its mate in growth until at 14 or 15 years the difference often amounts to several inches. Cases of congenital pes equino-varus will sometimes show considerable differences in the length of the limbs, tibia, and foot, and breadth of patella, after the lapse of some years.

In considering these results it should be remembered that not only is the affected limb underdeveloped in all the instances given, but that the sound limb may be overdeveloped, since it does far more than half, and often more than the normal amount of work, as is plainly evident from its circumferences. It is not impossible, though difficult to prove, that not only is the affected limb shorter than normal, but the sound limb may be longer as well as stouter than normal.

If so, this would exaggerate the difference between the two sides, and tend to make one overestimate the amount of retardation.

While there may be a primary neural factor in certain classes of growth retardation, and while disuse may produce its effect in part through the nerve centers, the writer is inclined, from a study of the facts here presented, to attribute to fixation, compression, and suspension of the affected limb, and to faulty or absent locomotion, an important role in growth retardation.

If this inference is correct, while one should not hesitate to make necessary sacrifices in order to promote the comfort of the patient, combat deformity, and to eliminate disease, it is not a matter of indifference how long the use of the limb is restricted. Protected locomotion, permitting joint and muscle action, with a minimum of strain and pressure, would seem to be indicated in the stage of convalescence from joint disease. That method of treatment, operative or mechanical, should evidently be selected which will give the best functional result with the least restriction.

A rather hasty search has revealed but few references to this topic in medical literature. Hüter makes some general observations on retarded growth of a limb after coxitis in his work on Joint Disease, published (second edition) in 1877. An excellent study, by Dr. Russell A. Hibbs, of shortening of the tibia and femur in 50 cases of tuberculous disease of the hip-joint, published in the *New York Medical Journal*, December 16, 1899, shows results similar to those here given.

Quite unexpectedly to the writer, and to some extent contrary to his preconceptions, this study, so far as it goes, appears to justify the following conclusions:

1. Considerable retardation of growth, both in the length and thickness of the limb and its component

bones, is the rule after coxitis, and other affections causing long periods of lameness or disability in childhood.

2. The amount of retardation appears to bear a distinct relation to the amount and duration of the restraint or disability.

3. This inhibitory effect of restraint should be considered in selecting treatment for disabling affections of the lower limbs. Other things being equal, locomotion is desirable, and restraint for long periods harmful, though complete or partial interference with function must often be enforced as the least of evils.

A REPORT OF A CASE OF RABIES.*

By FREDERICK KRAUSS, M.D.,

of Philadelphia.

Six weeks previous to the attack, Ida Z—, aged 8 years, fondled a sick dog, which her elder sister brought in from the street because it seemed to be suffering. Suddenly, without any warning, the dog bit her in the upper posterior border of the helix of the right ear.

The small wound bled rather freely, and was immediately cauterized by a physician in a neighboring drug store. The wound healed nicely, and no further attention was paid to the incident. The dog was thrust into the highway, and was lost sight of immediately after the child had been bitten.

Six weeks later, on Saturday, August 11, 1900, the child complained of toothache, lassitude, and was nervous. Her mother gave her a dose of castor oil, which operated freely. She passed a sleepless night, but did not complain until the next morning when her mother began to wash her, when she sprang back and complained of pain in her throat. This pain returned whenever she was touched about her face or throat with the wet towel, or even at the slight draught of air that was caused by the movement of the towel. At the breakfast table she tried to drink coffee, but could not on account of pain in her throat. As the child seemed to be well otherwise, the parents did not send for me until about 12.30 P.M., expecting the symptoms to pass away.

When, for the first time I saw her, near that hour, the child seemed very bright, but shy in manner. Her pupils seemed abnormally dilated, the tongue thickly and evenly coated, the breath very offensive. The temperature was 100° F.; pulse, 104. Her gait and manner seemed normal. When asked to drink water from a glass, she at first refused with an expression of dread, saying it hurt her throat so much, and made her short of breath. Upon urging she took the glass, and with sudden determination took a mouthful of water. Immediately that the water touched the pharynx, there was frightfully intense tonic spasm of the constrictors of the pharynx and other muscles of the neck, lasting from 10 to 15 seconds, and probably associated with a spasm of the glottis, as it was associated with dyspnea and followed by a gasping breath. Although some tonic spasm still remained, she succeeded in swallowing the small mouthful of water in repeated efforts after the more intense spasm had subsided. She suffered from extreme thirst, but each effort at drinking produced the same frightful result, thus causing her to suffer the punishment of Tantalus. Solids could not be swallowed. A slight, artificially produced draught of air caused a similar, though less marked attack.

During the intervals she was apparently only suffering from slight feverishness. The wound caused by the dog-bite was healed, the scar being slightly reddened. She passed a sleepless night in spite of large doses of bromide and chloral. On the following morning, August 13, 1900, she and her parents were delighted because of her ability to swallow, after much effort, about one-half glass of milk. The child thought she felt better; but her temperature had risen to 101.5°, her pulse being extremely rapid—130 per minute. She insisted that she was not afraid of anything, but was easily startled. She was led to think that she would get well, but at times she was haunted by a nameless dread of something. She still had the great pain, dyspnea and spasm in

her throat upon attempting to swallow. She was kept in bed and was fairly quiet until 4.15 P.M., when she suddenly sprang up and assumed a crouching position at the edge of the bed, with an expression of intense, horrible fear continuing upon her face, staring at the opposite wall, giving vent to short, unintelligent cries also expressive of fear. This lasted for one or two minutes, when she would wake as from a dream, fondle her mother, saying "she had thought she was near death then." She again laid down quietly for a few minutes, when a similar attack occurred. She always clung to her mother's waist, kissing her face repeatedly after each attack, and asking whether her mother loved her still. I asked her gently not to kiss her mother, as I feared a possible inoculation, and she immediately desisted. After a hypodermic injection of $\frac{1}{4}$ gr. of morphin with $\frac{1}{16}$ gr. of atropin, the attacks became less frequent. She was sent to St. Christopher's Hospital, during an *entire remission* of symptoms from 5.15 P.M. to 8 P.M. During this interval she was quiet and rational. Afterward she became restless; later extremely excited, throwing arms, legs, and even entire body about violently, losing all consciousness of surroundings, emitting short cries as though in fear, and trying to escape. These convulsive and maniacal attacks were relieved by inhalations of chloroform, but recurred after one-half hour's interval of stupor. During the attacks the pupils were widely dilated, the lips withdrawn from the teeth, and an expression of wild fear was upon the face. The pulse was rapid but strong. The temperature, respiration, and pulse were as follows:

	Temperature.	Pulse.	Respiration.
At 6 P.M.	103.0° F.	144	28
" 9 P.M.	104.6° F.	150	26
" 12 P.M.	102.8° F.	160	28
" 3 A.M.	103.1° F.	150	32
" 6 A.M.	101.8° F.	170	40

The patient received alcohol and water sponge-baths whenever temperature exceeded 103° F. The maniacal spasm, being most intense, was not affected thereby. Hypodermic injections of morphin were given to prolong the action of the inhalations of chloroform. The attacks of maniacal excitement continued until 6 A.M., when the patient became quiet and died at 7 A.M. of August 14.

The coroner was notified and a postmortem examination made by Dr. Wadsworth, who found severe congestion of the cerebral and spinal meninges, numerous punctate hemorrhages in the spinal cord, and a rupture of the pleura. A portion of the spinal cord was sent to Dr. Mazjick P. Ravenel, of the University of Pennsylvania, for diagnosis. In a private communication the latter says: "I have passed it through 4 generations of rabbits with positive results always. The examination of the intervertebral ganglion after the method of Van Gehuchten and Nélis, and of the bulb after Babe's method, confirmed the diagnosis positively."

In spite of the evidence presented, the coroner of Philadelphia, a layman, has entered the case upon the city health records as a case of convulsions, denying the existence of such a disease as hydrophobia.

The name hydrophobia appears to be a misnomer, as the patient was not afraid of the water, but of the painful spasm and dyspnea caused by the touch on the throat or upper part of chest of any liquid, or solid, or air—in other words, a centripetal impulse sent to the ganglion centers in the lower part of the medulla and upper part of spinal column, apparently the first portion of the cerebrospinal axis to become affected.

In the early stages, the suggestion to the patient that she should drink milk or water produced a slight spasm, in memory apparently of the terrible spasm caused by attempts to drink. Later on the sight of water was not especially distasteful, except that it was additional torture for the thirsty soul, who longed to drink and even asked frequently for a drink of water, but always found that she could not swallow without terrific and painful local spasm.

* Read at a meeting of the Northern Medical Association, January 11, 1901.

The prominent symptoms were the temperature, rapid pulse, deeply-coated tongue, offensive breath, slightly reddened but healed wound, lassitude, convulsive contraction, frightful in intensity, of the muscles of the neck and larynx upon the slightest peripheral irritation, dilated pupils, her tendency at first to be somewhat irritable, later very tender and loving as long as she retained consciousness. Later the intense fear and frightful convulsive movements of the body made in an apparent effort to escape from a most terrible vision, the convulsion being sufficiently great, indeed, to rupture the pleura, unconsciousness, and an apparent total absence of paralysis were the final features of this disease, so rare apparently in the human species in the United States.

Phloridzin Diabetes.—Seelig (*Deutsche medicinische Wochenschrift*) enters into a discussion of the exact role played by the kidneys in phloridzin diabetes. The most characteristic points of this form of diabetes are, that a glycosuria occurs after the injection of phloridzin, but instead of hyperglykemia, as in true typical diabetes, the sugar of the blood is not increased and may even be diminished. The two chief theories as to the production of this glycosuria are, that some change occurs in the kidneys which allows of the passage of the sugar; and, on the other hand, that the phloridzin is split up by the kidneys into phloretin and phlorose, and the free phloretin keeps continually uniting with sugar and being broken up again by the kidneys, the sugar being excreted and most of the phloretin for a considerable period going through the same cycle until ultimately all of it also is excreted. An observation made by Seelig is of interest in this connection. A rabbit which had been given one gram of phloridzin daily for four weeks, and had continuous glycosuria, was operated upon and one kidney removed for microscopic examination. The animal recovered, and secreted sugar for about 3 weeks without any more phloridzin being used. The iron chlorid reaction for phloridzin persisted 2 weeks after the sugar excretion had ceased. The glycosuria might be explained in this case by two means, it was either the result of the sudden extirpation of the kidney which had so reduced the excretory power of the remaining kidney that the phloridzin was excreted only with abnormal slowness, or it was produced by changes in the kidney, due to the phloridzin, from which the animal had recovered only very slowly because of the loss of the other kidney. This result, however, was obtained but once in a series of experiments. The occurrence of acetonuria is of interest in phloridzin poisoning and other conditions. Acetonuria occurs readily in men in inanition, and in various other conditions. Dogs do not show acetonuria as a result of any change in diet, but do readily show it as a result of phloridzin poisoning, or removal of the pancreas, and Seelig finds that the prolonged use of phloridzin does cause acetonuria in dogs but does not cause it in rabbits; nevertheless rabbits showed distinct necrosis in the tubules of the kidneys and they presented decided glycosuria. It has been claimed by some authors that the changes in the kidneys in phloridzin poisoning are due to the irritation of the acetone excreted by them. This Seelig claims is not true because of these observations on rabbits; there was no acetonuria, hence the necrosis must be attributed to the phloridzin, and he thinks the just conclusion from this is that the glycosuria was the result of these changes. One would expect if the epithelium of the canaliculi of the tubules of the kidneys were damaged by any other poison, glycosuria would not result from phloridzin poisoning. This is not the case. Various poisons have been used and followed by phloridzin, with the constant production of phloridzin glycosuria. This, however, cannot be used as testimony against the renal origin of glycosuria, as it is well known that very minute remnants of the organ may be sufficient to carry on its function fairly satisfactorily. Richter found that very small doses of cantharidin given subcutaneously produced glycosuria which gradually disappeared as an increasing albuminuria appeared. Large doses did not cause glycosuria. Seelig directs attention to the fact that Richter

observed that the glycosuria did not occur when the tubules were damaged, but did appear when the dose was so small that the tubules were left uninvolved, while the glomerules showed exudation and hyperemia. He explains this by stating that just as in phloridzin diabetes the glycosuria is a function of the renal epithelium, so must it be in cantharidin glycosuria, and if the dose of cantharidin has been so large as to destroy the epithelium the glycosuria will not appear. He considers that cantharidin in small doses has a severe effect upon the glomerules, but upon the tubules exercises only sufficient irritation to produce glycosuria. In discussing the cases in human beings which have been reported as renal diabetes he states that not one of these is truly such a case. That of Kolisch and Buber has been frequently considered to be true renal diabetes. Seelig, however, directs attention to the fact that glycosuria occurred only after taking food; it was not, therefore, a true diabetes, but merely a regulatory glycosuria, in other words an instance of tachyglycosuria.

The Connection Between Disease of the Uterus and Gastric Affection.—C. Tuszkai (*The Hungarian Medical Press*, No. 41.) Diseases of the uterus and stomach frequently coexist. A diagnosis of disease between these two organs is often difficult as symptoms may be referable to either viscus. This may be due, first, to the nerve tract, whose center is not in the brain or the spinal cord but in the sympathetic nervous system. From reflex action symptoms arise which relate to both organs. The reflex tracts being anastomosis spermatica, anastomosis pudendohemorrhoidalis, genitogastrica, cutaneocavernosa, and the nervi splanchnici. Also the anastomosis uteroceliaca and anastomosis uterospinalis. The immediate roads of the reflex tracts are direct connections of the vagus (excluding the ganglion solar) with the sympathetic nervous system. The second manner in which mistakes may occur are due to dislocation of the respective organs. The circulation only plays a minor role in this connection.

The Pathogenesis of Anemic Conditions in Childhood.—L. Fürst (*Therapeutische Monatshefte*, 1900, No. 9) believes that congenital anemia not infrequently is due to heredity. Habitual anemia of the parents, cachexia as a result of tuberculosis, malignant neoplasms, diseases during pregnancy, poor nutrition and lack of hygiene, may all, according to the author, give rise to anemia in the child. The anemia is transmitted by means of the placental circulation and continues to develop in the fetus in utero. The alimentary form when present in the nonanemic newborn is due to an exclusive milk-diet which in itself is deficient in iron. The anemia occurring from 5 to 12 years of age is characterized by rapid growth, loss in bodily fat, and is due to the increased processes of oxidation during which the formation of new blood-cells cannot keep pace with the increased tissue waste. The total amount of blood decreases because there is such a great demand upon hematogenesis to supply the new bone and muscle. The author describes a development-anorexia which is seen in both sexes during their school years, but which occurs especially toward puberty in the female between 12 and 15 years of age and is occasioned by an overexertion and overburdening of the brain, nervous excitation, and sedentary habits [M.R.D.]

Changes in the Spinal Cord in Pernicious Anemia.—W. Goebel (*Mittheilungen aus den Hamburgerischen Staatskrankenstellen*, Bd. II) reports the postmortem examination of 6 cases of pernicious anemia. In a child 5 years of age with the exception of a slight extravasation of blood into the frontal lobe, there was no degeneration of the brain or spinal cord. In older individuals there were some profuse degenerative changes in the cells, areas of disseminated myelitis pigmentation and degeneration of the ganglion cells (as a consequence of the cachexia) and in two cases changes were found in the extramedullary roots. The pia was always found in a delicate and normal condition with no changes in the bloodvessels to which the etiology could be ascribed. The changes in the gray matter were always less than those in the white and were absent entirely whenever the white matter seemed to be affected; the intensity of the affection of the gray matter was not in direct proportion to that of the white. The commissural fibers were intact. [M.R.D.]

Queen Victoria's Death.—The Queen's death evidently illustrated the truth of the old medical aphorism that a person's life is just as long as the life of the blood-vessels. Her Majesty apparently succumbed to the changes in the cerebral circulation, brought about by arterial sclerosis. This mode of death is very commonly seen in the aged, in whom, after death, it is not always possible to find gross or focal lesions in the brain. The most conspicuous pathological picture, as a rule, is the thickening and brittleness of the vessels forming the circle of Willis and its branches. The roughening of the inner coats of these vessels causes small thrombi to form; the lumen of the vessel is narrowed or obliterated; slowing or stasis of the blood-current results; more or less edema occurs, and nutrition and function are both seriously involved. The process once started probably spreads from one vessel to another. It is not necessary in every case that extensive necrosis or softening of the brain-substance should result. The clinical picture thus presented is that which is popularly called apoplectic, although it does not always come on with abruptness in its entirety. In the Queen's case there seem to have been successive attacks. According to apparently authentic reports, there was hemiplegia, or rather hemiparesis, the latter being the more common in these cases.

With the passing of Queen Victoria, a great epoch in English history closes, and one which has been conspicuous for the advances made in the medical sciences. Those advances, in their vast extent, cannot be chronicled here and now, and they are not especially associated with the personality of the English Queen, but they will long be associated with the period which bears her name. Towards the profession itself she was reputed to be liberal and broad-minded, and to some members of it she was deeply attached. It will be difficult for a long while to realize that the venerable sovereign, who has for so many years been associated in all minds with the power and prestige of the British Empire, is no more.

Infantile Scurvy.—Dr. Griffith's paper in the present number of the JOURNAL calls attention to the fact that infantile scurvy is rather more common than is generally supposed, and that it is capable of doing an immense amount of harm simply from the fact that it is so readily overlooked. This affection simulates a

number of diseases rather closely although superficially, but in the light which has been shed on it in recent years there seems to be no excuse any longer for an error in diagnosis. Scurvy is not rheumatism, and rheumatism is not scurvy, but the painful affection of the joints in both diseases is apt to mislead a careless or ignorant observer. Scurvy in infancy is a disease which is almost as easily cured in most instances as it is easily diagnosed. A simple exercise of common sense in returning the child to the kind of diet that nature originally intended for it, is practically all that is required in most cases. In other words, the correct diagnosis of the disease is nine points of the treatment, for when the disease has been once recognized the indications for treatment are plain and unmistakable.

While this is true Dr. Griffith very properly calls attention to the fact that although the cause of scurvy is clearly dietetic, yet there is no one dietetic fault that can alone be held responsible. It does seem, however, that a too large or too exclusive use of a farinaceous diet is often an etiological factor. Thus, as we called attention in these columns only recently, a rice diet has been found to cause this disease in Cuba. In this country there is no doubt a tendency toward a large use of commercial foods. It is probably true that when these foods are properly mixed with other ingredients, such as milk, which is essential to the welfare of the child, they are beneficially borne, and the risk is not so much that the physician but rather that mothers and nurses fall into the way of giving these foods too exclusively. They should be only a supplementary portion of the diet, not a mainstay. The collective investigation of the American Pediatric Society, made some years ago, proved the truth of this statement apparently beyond doubt. As to the sterilization of milk, it also is possibly a contributing cause, although Dr. Griffith evidently does not consider it an important one. It is well, however, for physicians to remember that milk which has passed through the process of cooking is not the kind of milk which nature originally intended for an infant. We trust that the exposition of this whole subject of infant feeding, which is given in the eminently useful and practical papers published in this number of the JOURNAL, will be of use to clarify this whole subject, as concerns both diagnosis and treatment, in the mind of the general practitioner.

Rheumatic Fever in Children and the Prevention of Cardiac Complications.—A strong argument in favor of the infectious nature of acute rheumatic fever is its behavior in children. As Heiman has pointed out in a recent paper (*Archives of Pediatrics*, January, 1901), the liability to joint involvement in children is reduced to a minimum, and, in certain cases, growing pains may be the only subjective symptom complained of. On the other hand, in the little folks, there is great danger of involvement of other tissues, particularly of the serous membranes, such as the endocardium. A short time ago Barbier and Tollemer reported to the Société de Pédiatrie (*Revue Mensuelle des Maladies de l'Enfance*, January, 1901) the case of a little girl aged 11 years who was suffering from an acute polyarthritis of 18 days' duration. This child was suddenly seized with aphasia and right-sided hemiplegia. After several days she died, and, at autopsy, a vegetating endocarditis of the mitral valve and multiple emboli in the cerebral artery were discovered. Realizing the danger of involvement of the serous membranes we should first place our patients under the most favorable conditions for the prevention of such a complication and then be on the lookout constantly for the first signs of endocardial mischief, so as to cure the lesion, if possible, before it becomes chronic. Caton ("The Prevention of Valvular Diseases of the Heart," London, 1900) has worked on this problem for 19 years and, in his book, gives the results of his studies and notes of 86 cases in which his method has been attended with a greater or less degree of success. For the prevention and cure of endocardial lesions this author has adopted the following method: His patients are clad in flannel night-gowns. They are kept in bed so as to secure complete physiological rest of mind and body, thereby reducing the demand made upon the heart to the physiological minimum. Pain is relieved by the salicylates. Small blisters are applied over the upper portion of the chest. These act in reality as direct stimulants to the vasomotor and trophic nerves of the ailing part. He exhibits the iodides and mercury as absorbents, and these drugs together with the salicylates are kept up for 3 or 4 weeks, or longer, if necessary, after the acute symptoms have subsided. He believes that those drugs that act directly and specifically on the heart, the so-called cardiac tonics, including digitalis and caffeine, are distinctly injurious. Heiman, in order to prevent the occurrence of endocarditis, gives from 3 to 5 grains of salicylate for one week of each month for a year or more after the acute symptoms have disappeared.

We believe that the strontium salt is the best form of the salicylates because it is the least likely to disagree with the stomach.

Caton emphasizes the fact that the mitral valve is affected much more frequently than the aortic—at least ten times as frequently in his experience. He explains

this by the mechanical principles involved at the time of closure of the mitral valve during each systole of the heart. At this moment intracardial pressure is immensely increased, and when the cusps come together they have to withstand this pressure. These cusps are nourished and repaired through connective-tissue channels, no bloodvessels existing nearer than the attached margins of the cusps. Under the strain and defective nutrition the infecting agent attacks the valves at their most vulnerable points. Counterirritation, he thinks, acts by influencing nutrition through the nervous system.

Enterocolitis.—The diarrheal diseases are exceedingly difficult to classify, as the severity of the symptoms are not necessarily dependent upon the gravity of the local lesions. Diarrhea may be defined as a condition in which soft or fluid evacuations occur frequently, the stool being either large or small. The fluid character of the dejecta is caused by an increase of the watery elements entering into their formation. This is primarily caused by the thin contents of the jejunum and ileum being poured too rapidly into the large intestine without being absorbed; or a massive transudation may occur from the wall of the intestine either from the bloodvessels or the lymph-glands. In the former case a reaction for bile is frequently obtained with nitrous acid, but not invariably. The presence of bile pigment in the stool shows absolutely that the diarrhea is dependent upon causes in the small intestine. Increased peristalsis either in the small or large intestine is the second factor upon which the occurrence of diarrhea depends. The pathological increase of peristalsis is dependent upon many causes. In the majority of instances, however, it is due to some anatomical morbid lesion of the bowel itself. This is, however, not invariably the case. Increased peristalsis may be due to the presence of irritating substances in the bowel, or in case that the contents of the intestines are normal, to an increased irritability of the nervous structure of the bowel (the ganglion or the sensory nerve); or the central nervous system may be at fault; or toxic substances may be present in the circulation which increase peristalsis. Any one of these causes are sufficient to produce the symptom-complex known as diarrhea. It is, however, probable that several of the causes acting together give rise to the condition.

It is now generally conceded that acute enterocolitis is almost invariably the result of microorganisms, their toxins or a combination of both. Hence the affection should properly be considered a toxemia, and although inflammatory changes arise in the bowel they are not the cause but the result of the influence of the bacteria and the ptomaines. No specific bacterium has as yet been isolated. The means by which the microorganisms gain access to the susceptible gastrointestinal tract is undoubtedly by way of the mouth. The ho

season has been given as a marked predisposing cause for this affection. This is true in so far only as heat increases the development and activity of the organisms which are productive of this affection. Almost every practitioner has seen cases of severe enterocolitis arising in children in the cold months of the year in which food unquestionably and not heat was the etiological factor.

The treatment of the affection should consist first and foremost in ridding the individual of the cause of the affection. The physician who treats symptoms will often disregard this in paying attention only to the prominent symptom of the affection, the diarrhea, and attempt to check this. The contents of the intestinal tract should be properly evacuated. This may be best accomplished by the use of castor oil, calomel in broken doses, or a saline. If these are not retained and vomiting be a principal symptom, as it sometimes is, enteroclysis of water often satisfactorily accomplishes the same purpose. If high temperature be a marked symptom, ice water may be used for this purpose. Opium as a routine treatment is dangerous, especially in children under one year of age. The use of some intestinal antiseptic, such as salol, or the bismuth salts in large doses, is considered good practice. A valuable adjunct to the treatment, besides most careful attention to the diet, consists in a change of climate. A high mountain climate, or preferably the seashore, will in many instances, without any further medical treatment, especially in the milder cases, promote a rapid recovery.

Hysteria in Children.—Oppenheim, in his work on nervous diseases—recently translated into English by Dr. Edward E. Mayer, of Pittsburg—calls rather more pointed attention to this subject than used to be the custom in textbooks. The old fallacy that hysteria is an affection of the morbid womb, has been most tenacious, and it naturally excluded children from the sphere of this disease. The recognition of hysterical phenomena in children has therefore been a long time coming, and even yet the disease as it affects children is not accorded due notice, as a rule, outside of special treatises. Oppenheim seems to have had a unique experience, for he tells us that he has repeatedly observed hysteria in children of from 2 to 3 years of age. He also saw the disease successively in 4 children of an hysterical father—a fact which illustrates the now well-known heredity of hysteria. Clouston's statistics, based upon 272 cases, include but one authentic case at the early age of 3 years. In fact, until 7 the disease is rare. Oppenheim even goes to the extent of attempting to establish an analogy between infantile convulsions of the ordinary type and the hysterical crises of adults. Both, he thinks, are due to incomplete development of the inhibitory centers. The child's brain, therefore, is analogous to that of the adult hysteric. This is rather an unhappy attempt at

finding analogies, and may mislead some students. It also shows that German neurologists have not yet acquired the clear analytical view of hysteria, which characterizes the French writers, for infantile convulsions are very unlike the convulsions of true hysteria (whether in the child or in the adult) and are more to be compared with epilepsy. They are probably of toxic origin, and are marked with a profound unconsciousness that differs from that seen in hysteria. They are common, too, as a rule, in much younger children, and they are not associated with, or followed by, the permanent stigmata of hysteria.

The chief importance of this subject to the general practitioner arises from the fact that this psychoneurosis may sometimes complicate in a most confusing way the picture of organic disease. It is not that hysteria simulates organic disease, but that it complicates it; this is the important fact. The difficult task is to differentiate, to disentangle the organic from the psychic. By failing to do this, grave errors may arise, not only in diagnosis, but in treatment. It is true, finally, as Oppenheim has not failed to recognize, that hysteria may complicate one of the other neuroses; thus, in young children, an infantile convulsion, of the ordinary type, due to toxemia, may be followed by the manifestations of hysteria. In such cases it is needful to exercise unusual care and acumen in order to make a correct diagnosis.

The Disorders of Dentition.—We shall confine ourselves to the morbid conditions associated with dentition, rather than any abnormalities in the teeth themselves or their period of eruption. A wealth of clinical experience has shown the frequent coexistence of certain diseased states and the process of dentition. Yet our seer has set us the watchword through the centuries that experience is often "fallacious," and no doubt a host of conditions have been ascribed improperly to dentition which have had nothing whatever to do with the process, the fault being, not of our experience, but its interpretation.

We are confronted by two extreme views upon this question. It was the habit formerly to blame dentition for practically all of the ailments from which a teething child suffered. This led to numbers of cases of neglect of timely treatment, it being believed generally by the laity and even the profession that such ailments would be quite relieved when the offending tooth was cut. Again, it has been too often declared that a little patient *with its 20 milk teeth*, and under the age of second dentition, was ill merely from teething. This is an error arising from the lack of elemental knowledge.

Jules Comby, of Paris, and many others hold that dentition being a strictly physiological process has no diseases dependent upon it. We believe with Vogel, of Dorpat; E. Henoch, of Berlin, and others that the

middle ground is the sound one. It is difficult to believe that all of the coexisting morbid conditions associated with dentition are accidental. We know that inflammatory conditions of the buccal mucous membrane may, at times, be local, but are often general and may give rise to a stomatitis, either of the catarrhal or aphthous form. Extension of the inflammatory process, and the reflex irritation thus caused, have been held accountable with some degree of authority¹ as a cause of acute anterior poliomyelitis and possibly spinal meningitis.² The excessive dribbling of saliva often wets through the child's garments and gives rise to a coryza and bronchitis, which might also very readily arise from extension of the inflammation of the mucous membrane to the upper and lower air-passages. Swallowing quantities of saliva causes a form of diarrhea prevalent during dentition and gastric and gastrointestinal disorders. The mere presence of a local inflammation is sufficient exciting cause of the frequent elevation of temperature observed. This, however, in these cases is not usually alarming.

The occurrence of skin eruptions associated with the cutting of certain groups of teeth and subsiding when the teeth have appeared is too familiar to be gainsaid. These include urticaria, occasional lichen and prurigo, eczema and impetigo. Nor must we forget the crusta lactea of the hairy scalp.

The nervous system of an infant is disturbed easily by reflex influences, and most important are the convulsive phenomena varying from slight twitchings to pronounced eclampsia. Henoch has observed a partial contraction of the muscles of the throat and neck during dentition, due to nerve irritation. Competent authorities have called our attention frequently to the presence of an otitis media of which dentition has been the causal factor, and we must not overlook the conjunctival blennorrhea associated with the cutting of the canine—or very properly named “eye” teeth. The precise connection of cause and effect in these cases is often difficult to trace. That a physiological process should give rise to such manifold complications raises the spirit of doubt in many minds. But the incontrovertible repeated association of certain conditions with the process of dentition forces us to ascribe an etiological rôle to the process itself, whether the cause be exciting or predisposing.

The question is somewhat vital at times, for many apparently serious conditions, in which the cause is unrecognized, might induce a method of treatment quite inappropriate; for instance, in treating a conjunctival blennorrhea or an otitis media radically, when the cause is resident in the cutting of a tooth in a class of cases in which recovery will occur promptly when this has been accomplished. Again, it is important to guard against the misinterpretation of certain gastric or gastro-

intestinal disorders in which the recognition of the cause is far more important than routine treatment, with the cause constantly operative. The value of lancing the gums as a routine measure is quite generally deprecated, but in certain conditions the local depletion and the relief of tension thus brought about will be of the greatest service.

Rubeola and Rubella.—If one consults the medical dictionaries he finds that the word rubeola receives two definitions. The first makes it a synonym for rubella, or that which is more commonly known in this country as German measles, and the second gives the word as a synonym for measles. There is, therefore, some confusion as to the proper significance of the terms rubella and rubeola. Jürgensen (Nothnagel's Special Pathology and Therapeutics, Vol. V, Part II) shows that rubella is a nosological entity, and that it has nothing to do with either measles or scarlet fever. Furthermore, the majority of recent writers describe the two diseases separately. The following, as is well known, are the chief differences between measles and rubella:

In measles the period of incubation is from 5 to 14 days, or an average of about 12 days, while in rubella, or German measles, this period is from 7 to 21 days. In measles the onset is gradual with anorexia, fever, and marked catarrhal symptoms, while in rubella the onset is usually without symptoms until just before the rash appears. Enlargement of the cervical, axillary, and inguinal glands is very common in the latter. In measles the febrile stage is rather more pronounced than in rubella, and in the former disease the eruption does not appear until the fourth day, whereas in rubella it appears on the second day. This eruption in measles is coarse, papular, dark red, and much more pronounced than in rubella. Finally, there are many more complications or sequelae in measles than in rubella. Among these complications are the following: Purulent conjunctivitis, stomatitis, bronchitis, catarrhal pneumonia, otitis media, and intestinal derangements. One way out of the difficulty caused by this unfortunate misuse of terms would be to always use the word rubella to signify röteln or German measles, but a still better way would be to drop the term rubeola altogether and refer to the two diseases as measles and rubella. We doubt, however, whether any of these Latin terms, namely roseola, rubella, and rubeola, will ever become popular with the profession. Even now many of the best-read men will hesitate a moment if they are asked for a prompt definition of these individual terms. On the other hand the terms measles and röteln, or German measles, are perfectly well understood, and are not liable to be mistaken.

The Etiology of Yellow Fever.—Since the paper on the etiology of yellow fever, by Reed and his co-workers, appeared in the PHILADELPHIA MEDICAL JOUR-

¹ Erb. ² Erb.

NAL of October 27, 1900, these investigators have diligently pursued the study, and, in the issue of this journal of December 22, a telegram from Dr. Reed to the surgeon-general of the army stated that inoculations had been successful in 80% of cases. Carlos Finlay, of Havana, is the author of the theory of the transmission of yellow fever through the agency of *Culex fasciata*. As early as 1891 this author stated, in a paper which was published in part only, in 1892, that the first idea of the mosquito as the habitual agent of the disease arose from the difficulty of accounting for the propagation of yellow fever upon any supposition but that of an infection produced by a natural inoculating agent which should first become contaminated from a yellow-fever patient and afterward communicate the disease by inoculating susceptible persons with the germs which it had picked up and retained. Bérenger-Féraud attacked the theory on the ground that an epidemic propagated from Havana to Saint-Nazaire through the *Anne-Marie*, in 1861, could not possibly be thus accounted for. In the *New York Medical Journal*, January 19, 1901, Finlay explains this epidemic according to the mosquito theory. It seems that the *Anne-Marie* left Havana on June 13, 1861, manned by the same crew that had navigated her from France to Cuba one month before. At the beginning of the return voyage the vessel was becalmed for 12 days in the Florida channel, with suffocating heat, frequent squalls, and heavy rains. On the first and second of July, 1 nonfatal and 2 fatal cases of yellow fever developed among the crew; these 3 men must have been infected before the ship left Havana. Between the fourth and the eighth of July, 6 new cases developed, of which none was fatal. With the loading and the provisioning of the ship it is highly probable that a considerable number of mosquito eggs and larvae were introduced on board, and that a whole brood of new mosquitoes was produced on the vessel while she was becalmed during the first 12 days of her voyage, and that by stinging the first 3 patients taken ill, some of them infected the next 6 men who were prostrated. At this time the calms had ceased and the vessel had reached cooler latitudes, which, together with the attraction of the sugar, caused the insects to take refuge in the hold. No new cases developed on the voyage to France; but when the hold was opened at the wharf at Saint-Nazaire, on July 27, the inoculated mosquitoes began to sting all the nonimmune persons who came within their reach, 19 in all, and all of these contracted the disease. Five other persons appear to have taken the infection on the wharf or on the decks of other vessels in close proximity to the infected ship. The infection of 4 other persons who were not near the ship is accounted for. Owing to climatic influences unfavorable to the development of new broods of mosquitoes, the brood hatched on the ship early in July would have become extinct during the second week of August, and, in point of fact, the epidemic ceased at that time. The chain is also traced to

the *Arequipa*, a ship moored next to the *Anne-Marie* at Saint-Nazaire. The mosquito theory of the transmission of the disease has been attacked by Wasdin (*PHILADELPHIA MEDICAL JOURNAL*, November 17, 1900), principally because Reed and his fellow laborers have failed to isolate the *Bacillus icteroides* from their patients. We see, however, no reason why the mosquito theory of transmission of the disease is incompatible with Sanarelli's theory of the specificity of the microorganism. While the work of Sanarelli is most valuable, his organism has not been finally accepted by the profession as the cause of yellow fever. Neither has the profession accepted the new theory of the transmission of the disease. We should be ready to be convinced by competent observers both that the *Bacillus icteroides* is the cause of yellow fever and that it is carried from one person to another by mosquitoes.

Prager medicinische Wochenschrift. — It again becomes our pleasant duty to congratulate one of our contemporaries across the sea. The beginning of this century marks the twentieth-fifth anniversary of the *Prager medicinische Wochenschrift*. With its present contributors and the high-grade character of its articles, it cannot fail to maintain its position in medical journalism.

Douglas Abscess in Perityphlitis.—Rotter (*Deutsche med. Wochenschrift*, Oct. 4, 1900) says that among the abscesses caused by perityphlitis the most frequent is (1) that of the pelvic cavity; (2) the Douglas abscess; (3) that of the lumbar region; and (4), the rarest, the subphrenic abscess. Out of 182 cases of perityphlitis he reports 41 of abscess in the Douglas cavity, or about $\frac{1}{4}$. He defines a Douglas abscess as one which has its base in the peritoneal folds of the Douglas sac, and, increasing, reaches the intestinal loops above, which, when adherent, form a covering for the pus cavity, separating it from the abdominal cavity. The Douglas abscess is formed when the perforation of the appendix permits the infecting material to scatter through the abdomen and sink to the lowest point, the base of the Douglas fold. It occurs in case of a fresh, circumscribed perityphlitic suppuration in which there is a serous outflow into the peritoneal cavity accompanying a general peritoneal inflammation, and this fluid collecting in the Douglas pouch becomes infected. A frequent symptom accompanying a Douglas abscess is a distended abdomen with severe suffering of the patient, simulating the symptoms of a diffuse peritonitis; but these symptoms are the result of the pressure of the abscess upon the rectum and other organs, causing constipation, etc., and they diminish as soon as the abscess is emptied. In women it is often difficult to determine whether the Douglas abscess is caused by disease of the appendix or of the generative organs, but Rotter believes that when the contents contain colon bacilli it is of perityphlitic origin. The diagnosis of the Douglas abscess is comparatively easy and certain by means of rectal examination, and this is the best method by which to ascertain the proper operative treatment; for when the presence of an abscess is no longer in doubt, there can be no other treatment than operative. In women the incision can usually be made through the posterior vaginal wall, though in young girls Rotter prefers to reach the Douglas abscess through the rectum. If other abscesses are found to exist which cannot be emptied through the Douglas sac an abdominal incision becomes necessary; but this involves the danger of spreading the infection and causing peritonitis, only to be avoided by the greatest care and surgical cleanliness. [W.K.]

Correspondence.

PARTIAL TRAUMATIC PARALYSIS OF THE TRIFACIAL NERVE.

BY HENRY M. FISHER, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

MICHAEL S., while working in a stable one month ago, was struck by a companion with a pitchfork. One of the prongs of the fork caused a pretty severe lacerated wound of the mucous membrane of the right cheek and the other made a penetrating wound of the left lower eyelid about one-third of an inch to the left of the middle of the eyeball. He was taken to the Pennsylvania Hospital where the wound of his right cheek, which was bleeding profusely, was sutured.

For two or three days there was complete anesthesia of the left side of his face and he experienced difficulty in speaking and in swallowing. Anesthesia is no longer absolute on the affected side, but even now, if he does not pay strict attention, part of his food regurgitates through his left nostril.

No hemianesthesia of the tongue. For a few days hearing was slightly impaired in the left ear and even now he experiences occasional deafness on that side.

ABOUT THE RED BLOOD-CELL.

BY M. GIRSDANSKY, M.D.,

of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE human red blood-cell is ordinarily described as "a circular, biconcave disc, with rounded edges, composed of a colorless, structureless, and transparent filmy framework or stroma. (Kirke's Physiology.)

When, however, the red blood-cell is destroyed, as, *e. g.*, in "laky blood," it appears under a high power "as an obscurely spongy reticulated disc," which may be stained by various reagents (Foster).

This is all more or less ancient history, and, of course, very well known to all of us.

Under the following procedure the red blood-cell will appear as a beautiful fenestrated reticulum, somewhat resembling the foliated tracery of Gothic architecture:

With the ordinary precautions of cleanliness, make a thin spread of newly-shed blood in the usual manner. Fix the film either by leaving the slide for 2 hours in a mixture of equal parts of absolute alcohol and ether, or by gently heating the slide over the flame of an alcohol-lamp for a few minutes. Flood the slide with the following solution:

Saturated alcohol-solution of methylene-blue,	3 parts.
Water.....	3 parts.
Absolute alcohol.....	3 parts.
Carbolic acid, C. P.	1 part.

Mix; wash it in a gentle stream of water and restain with

Eosin—sat. alcohol-sol.....	1 part.
Water	10 parts.

Mix; wash it in a similar manner and restain with Loeffler's solution:

Concentrated alcohol-solution of methylene-blue.....	30 parts.
1:10,000 watery solution of caustic potash.....	100 parts.

Mix; wash in water, dry and examine without cover-glass in cell or oil with a $\frac{1}{2}$ oil-immersion lens.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. Edward Stieren of Pittsburg, Pennsylvania, has been appointed ophthalmic surgeon to the McKees Rocks General Hospital.

Dr. Charles A. Oliver has recently received the honorary degree of A.M. from Lafayette College and has been made one of the honorary vice-presidents in the section of ophthalmology at the Third Pan-American Medical Congress.

State Board Examination.—Eighty-seven applicants for medical diplomas took the examination before the board of medical examiners of the State Medical Society of Pennsylvania at Philadelphia last December, and 48 passed, 35 failed, 2 withdrew and 2 were disqualified.

German Hospital Election.—The annual meeting of the trustees of the German Hospital was held January 29, and the following officers elected for the ensuing year: President, John D. Lankenau; vice-president, M. Richards Macklé; secretary, Rev. F. Wischan; treasurer, Charles Woerwag; solicitor, Joseph A. Rosengarten. The entire medical staff was reelected.

Results from Antitoxin.—A report prepared by the Lancaster Board of Health, relative to the use of antitoxin in treating diphtheria, shows the following results: Last year 262 cases of diphtheria were reported to the board of health, of which number 28 resulted fatally. In 1892, when antitoxin was unknown, 260 cases were reported, and there were 63 deaths. In 1895 there were 229 cases and 68 deaths, and in 1897, 197 cases and 38 deaths.

Philadelphia Polyclinic.—At the annual meeting of the corporators of the Philadelphia Polyclinic, the following trustees were elected: William K. Donovan, Judge Ashman, Franklin B. Kirkbride, J. E. Sterrett, Hon. Henry K. Boyer, George T. Lippincott, Nathaniel B. Crenshaw, William F. Read, C. S. W. Packard, Henry B. French, Nelson Z. Graves, John Scott, Jr., and James Crosby Brown. Miss Marie Blanchard and Mrs. Thomas S. Kirkbride, Jr., were elected members of the corporation. Dr. Howard F. Hansell, President of the Faculty, presented a report covering the medical work of the institution during the past year, and Miss Banfield, Superintendent of the Hospital, presented a report of the hospital and training schools.

Additions to Hospital Staff.—At the meeting of the Department of Charities and Correction, January 24, there were 13 additional members appointed to the medical board of the Philadelphia Hospital. The board is constituted as follows:

Surgeons.—Drs. W. Joseph Hearn, L. W. Steinbach, Orville Horwitz, Ernest La Place, Edward Martin, J. C. DaCosta, Alfred C. Wood, Charles H. Frazier.

Physicians.—Drs. R. G. Curtin, J. H. Musser, F. P. Henry, W. E. Hughes, S. Solis Cohen, J. L. Salinger, James Tyson, Thomas G. Ashton, A. A. Eshner, Alfred Stengel, H. B. Allyn, David Riesman.

Ophthalmologists.—Drs. Barton C. Hirst, Edward P. Davis, George Y. McKewey, J. M. Fisher, R. C. Norris, W. Frank Hachman, Elizabeth L. Peck, John B. Shober.

Obstetricians.—Drs. C. K. Mills, F. N. Deroun, Charles W. Barr, F. Savary Pearce, William G. Spiller, Charles S. Potts.

Ophthalmologists.—Drs. G. E. deSchweinitz, Charles A. Oliver, Howard F. Hansell, John W. Cheskey.

Dermatologists.—Drs. W. H. Stelwagon, H. B. Hartzell, E. S. Gans.

Pathologists.—Drs. W. M. L. Coplin, Joseph McFarland, Simon Flexner.

Pathologists.—Dr. L. N. Boston.

Pathologists.—Drs. George Morley Marshall, E. B. Gleason, Charles P. Grayson.

Anesthetists.—Dr. Charles Leonard.

Pathologists.—Drs. R. H. Nemes, M. H. Cryer, I. Norman Broomall, C. Stelwagon, Jr.

Pediatricists.—Drs. William C. Hollopeter, E. E. Graham, J. P. Crozer Griffith, J. Madison Taylor.

Orthopedic Surgeons.—Drs. H. Augustus Wilson, J. P. Mann, G. G. Davis.

Registrars.—Drs. Joseph Sailor, William C. Pickett, Robley D. Newton, B. Franklin Stahl, W. A. N. Dorsland, J. H. McKee.

The present corps of 50 outdoor physicians, consisting of 1 regular and 1 homeopathist to each of the 25 districts into which the city is divided for this purpose was reappointed.

Vital Statistics of Philadelphia for the week ended

January 26, 1901:

Total mortality	536	
	CASES.	DEATHS.
Inflammation of appendix 3, bladder 1, brain 14, bronchi 12, kidneys 24, lungs 68, peritoneum 7, stomach and bowels 15, spine 2, of larynx 1, of liver 4, pleura 1, nerves 1		153
Inanition 13, marasmus 9, debility 4		26
Tuberculosis of lungs		53
Apoplexy 25, paralysis 16		24
Heart—fatty degeneration of 3, neuralgia 2, other diseases of 34		39
Uremia 11, diabetes 4, Bright's disease 13		28
Casualties		11
Carcinoma of breast 2, stomach 5, uterus 3, face 1, bladder 1, neck 1, back 1, bowels 1, rectum 1, liver 1		17
Convulsions		10
Diphtheria	101	15
Brain—softening of 1, congestion of 1		2
Typhoid fever		16
Old age		16
Burns and scalds		2
Dysentery		1
Suicide		5
Cirrhosis of liver		5
Alcoholism		1
Cyanosis		3
Scarlet fever	75	4
Influenza		10
Abscess—of brain 1, of head 2, psoas 1		4
Asthma 3, anemia 3, congestion of the lungs 2, carbuncle 2, cellulitis of neck 1, croup 1, membranous croup 5, diarrhea 1, drowned 1, epilepsy 2, erysipelas 1, senile gangrene 1, of the foot 1, hemorrhage from lungs 1, homicide 1, jaundice 1, leukemia 1, obstruction of the bowels 3, edema of lungs 2, purpura hemorrhagica 1, retention of urine 1, arterial sclerosis 2, surgical shock 4, septicaemia 1, sarcoma 1, of the chest 1, stricture of esophagus 1, tumor of abdomen 2, of brain 1, ovarian 1, ulceration of the stomach 3, whooping-cough 1, gastric fever 1		32

Philadelphia County Medical Society.—At the stated meeting, held January 23, DR. ALBERT E. ROUSSEL reported 3 cases of malignant endocarditis. In Case 1 the disease followed measles. In Case 2 the patient was but 9 years of age and was convalescing from a typical attack of typhoid fever. During the attack of endocarditis the temperature was mostly subnormal, rarely rising above 101°. There was enlargement of the axillary and cervical glands, a leukocytosis of over 50,000 with the presence of poikilocytes and macrocytes, and the spleen extended below the umbilicus. Autopsy showed valve lesions and infarcts in the spleen and liver. The case was reported as one simulating leukemia. Case 3 terminated in recovery. This naturally threw some doubt on the diagnosis, but this was believed to be correct because (a) the patient had shortly before passed an examination for life insurance; (b) during the attack multiple abscesses were opened in various parts of the body and these contained streptococci; the blood also contained streptococci; (c) the heart lesion has persisted since the attack, as shown by murmurs. In discussing the paper DR. JAMES TYSON said he had seen no recoveries and had come to think the recovery of a case meant error in diagnosis. As to the terminology, he would class cases as simple infective and malignant infective. DR. J. M. ANDERS said the chief interest lay in the diagnosis. Sometimes a reasonably certain diagnosis can be based on a septic temperature, murmurs, and embolic symptoms even though there be no primary disease to suggest endocarditis. Visceral and cutaneous embolism are the most important diagnostic points. In obscure cases a diagnosis by exclusion from typhoid fever, cerebrospinal fever, and malaria, can now be made by methods not formerly in vogue, as blood examinations, lumbar puncture, etc.

DR. J. H. B. ROBERTS read a report of two cases of **epi-
ploxy in cirrhosis of the liver** and described the technique of the operation which he uses. Both cases died, one in 6 months, the other the day following the operation. Dr. Roberts stated that it was yet too early to know the real value of operation in these cases, but as the operation itself is a trivial one and the disease is so intractable early operation seems advisable. The operation is done under local anesthesia, an incision being made above the umbilicus and a finger introduced to hold the omentum against the abdominal wall. Sutures of chromicized catgut are then passed by

a long curved needle which penetrates the skin, abdominal wall, and omentum, coming out through the skin about an inch from the point of insertion. The abdominal wall or omentum should not be rolled up as this makes the stitches liable to tear out. The omentum should also be anchored in the wound when the abdominal incision is closed. This operation should be done as soon as practicable after the diagnosis is made. DR. TYSON stated that he had had one obstinate case operated upon, the patient leaving in 2 or 3 months apparently cured. The impression made by this case was a favorable one and he is inclined to encourage the procedure in selected cases. DR. W. M. L. COPLIN considers it a question as to whether anything is gained by short-circuiting the portal circulation. At autopsy, in cases of cirrhosis, a subcapsular vein is often seen through which a probe can be passed from the portal to the hepatic vein. One case was cited in which ascites ceased after the patient had been tapped at various times during several years. Autopsy showed a tortuous vein on the under surface of the liver connecting the portal and hepatic veins, yet the patient died. If operation is to relieve ascites it is effective. If it is to overcome the condition causing ascites it does not promise so much. DR. ERNEST LAPLACE said that in these cases the liver was already incapacitated for doing work and so differed from experimental cases where the liver function was suddenly stopped. He believes the operation is a rational one. It does not cure the patient but prolongs life.

DR. ALBERT BERNHEIM read a paper on **Albuminous nutrition and nutritious albumin-tropon**. Several cases illustrating the value of tropon were cited.

A paper by DR. L. F. FLICK, **The summer cold; swimming-pools as an etiologic factor**, was read by title.

Pathological Society.—The meeting of January 24 was devoted to a **Symposium on diabetes**. DR. D. L. EDSALL spoke on **The metabolism of diabetes**. The speaker stated that the disease was a partial starvation affecting the carbohydrates of the food. The sum total of metabolism in a case of diabetes is normal. The excessive output of nitrogen has been explained in 3 ways: (1) It is the result of taking in large quantities of nitrogenous food; (2) it is the result of some toxic or nervous excitant; (3) not enough food is taken in and the tissues are breaking down. The last may be proved correct by putting the patient on a nitrogen balance. As a rule, there is no disturbance of digestion. Alimentary glycosuria is the condition most closely resembling diabetes, but differs from it in the following particulars: (1) Alimentary glycosuria is purely dependent on the taking of sugar in over amounts; (2) it does not tend to increase; (3) the sugar excreted is the same kind that is taken; (4) only carbohydrates will cause it.

DR. EDSALL spoke for DR. SIMON FLEXNER (who could not be present) on **The relation of the kidney, liver, and pancreas to diabetes**. Concerning the kidney it was stated that there is no satisfactory evidence of glycosuria without hyperglycemia. Pathologically, there is no evidence that the kidney is related to diabetes in a causal way. The so-called hvalin degeneration of the kidney is a deposit of glycogen. As to the liver there are pathological alterations in a large number of cases of diabetes, but they are of much greater frequency when diabetes is not present. Dr. Flexner has stated that he can tell a diabetic liver by looking at it owing to a peculiar appearance of the organ. There is no conclusive clinical evidence that the liver is a cause of diabetes and experimental results are against it. It is, therefore, probable that it is not a primary cause but is accessory and intensifies the condition if there is liver disease in connection with diabetes. As to the pancreas, the results of experimental work with animals show that diabetes is inevitable if the pancreas is removed. This result is avoided if only a small part of the organ be left. Some observers state that in diabetes there is a sclerosis surrounding the islands of Langerhans in the pancreas. This has not been proven.

The paper of DR. JOHN MARSHALL on **The chemistry of the urine in diabetes** was read by DR. A. C. ABBOTT. The various tests for sugar were reviewed and their errors pointed out. Especial attention was called to the fact that formaldehyd, chloral hydrate, and chloroform will reduce cupric to cuprous oxid. The various phases of the subject of the evening were discussed by DRs. WADSWORTH, RIESMAN, COPLIN, DALAND, WILSON, McFARLAND and SHUMWAY.

Neurological Society.—The meeting of January 28 was devoted to a **symposium on brain tumors**. DR. WHARTON SINKLER reported two cases of **paresis with symptoms of brain tumor**. Attention was called to the fact that in some cases of paresis almost typical Jacksonian convulsions occur. Later on in the disease hemiplegia, and at times aphasia, occur. In these cases when mental symptoms are not prominent it is difficult to believe that brain tumor is not present. Two cases illustrating this point were detailed. DR. F. X. DERGUM gave the history of a colored boy, 12 years of age, who had **hemiplegia, homonymous hemianopsia, and Wernicke's symptom**. Autopsy revealed a large irregular mass in the left occipital region, subcortical, which cut off the fibers of Gratiolet and interfered with the optic thalamus. Wernicke's symptom was probably due to pressure. DR. JOHN K. MITCHELL reported a case of **extensive endothelioma of the brain**. Points of interest in the case were: 1. The long period of growth, symptoms being prominent for about 9 years. 2. The intermittent character of the symptoms. There were intervals of days and even weeks when absolutely no symptoms were present. 3. A period of temporary improvement followed the use of iodids. 4. The large size of the tumor, which measured 7 by 8 cm. DR. CHARLES K. MILLS spoke of the **localization of brain tumors** with special reference to the parietal and prefrontal regions, 5 cases being cited. The importance of sensory disturbances before motor phenomena appear was strongly emphasized, as it is largely by these, with visual changes, that the diagnosis is made. Another point to be remembered is that every tumor of considerable size invades some locality other than that in which it originates. The reflexes show this well. Take the Babinski reflex when the tumor is in the parietal region. If there is not much pressure this reflex will not be present. As the tumor grows toward the motor region the plantar reflex changes. The same is true of ankle clonus which comes on as the tumor invades brain tissue. There is a difference in the sets of phenomena depending on which cerebral hemisphere is involved, there being a more distinct disordering of the muscle sense when the lesion is in the left hemisphere. DR. A. A. ESHNER exhibited for DR. DAVID RIESMAN a case showing **unilateral oculomotor palsy probably due to a gumma**. DR. W. W. KEEN, in opening the discussion, spoke of the advantage of the large osteoplastic flap. In one case he turned down a rather triangular-shaped flap, the apex of the triangle being below and very small. A sign elicited in one case was a cracked-pot sound, which could be elicited from the frontal region to the binauricular line. This was due to the bones forming the coronal suture being slightly separated by the pressure of the tumor. The amount of injury that can be inflicted upon the brain without ill results is very great. In a recent case the lateral ventricle was opened, this being recognized by the change in color of the blood due to admixture with the fluid of the ventricle. No untoward symptom followed. The early recovery of motor-function after an operation is noticeable, one boy moving his previously paralyzed arm and leg within 48 hours after the operation. One surgical problem is difficult to solve—the avoidance of both hemorrhage and fungus cerebri. Two of the five cases reported by Dr. Mills (all of whom were operated upon by Dr. Keen) died, one from shock and the other from hemorrhage. This hemorrhage was oozing which followed the operation. Drainage would perhaps have saved that patient, but one is tempted to close the wound without drainage in these cases in order to prevent fungus cerebri. Warned by the case lost, however, drainage of gauze was used for 24 hours in a case operated upon a few weeks since. Despite the early removal of the gauze, fungus cerebri is now threatening. This, however, is more readily dealt with than is hemorrhage. Nothing will be done with the condition should it develop except a daily dressing and cutting it off even with the scalp. One case healed perfectly by thus treating it conservatively. In very large tumors it is desirable that the operation be done in two stages. The importance of early operation was strongly urged. The family physician or neurologist is the first to see these cases. If treatment for 6 weeks—almost always by the iodids—causes no improvement operation should be done at once. DR. W. J. TAYLOR said that there was always more danger from venous than from arterial bleeding. A point in the operation

is the determination of the thickness of the skull. DR. KEEN now usually makes a preliminary opening with a small trephine for this purpose. The flap is then made with chisels. DR. G. E. DESCHWEINITZ spoke on changes in the eye caused by brain tumors. From statistics published it is safe to say that optic neuritis occurs at some period during the course of at least 78% of brain tumors. Personally, DR. DESCHWEINITZ believes that the percentage is larger than this. Tables giving the relative frequency of location were read. It has been said that two regions are never affected—the hypophysis and medulla. The former is incorrect. Death from tumors of the medulla comes too soon to allow of optic neuritis. This condition may be unilateral. When so it is 4 times as frequent on the affected side. Choked disc is not always present, the inflammation taking the form of a papillo retinitis. The star-shaped figure seen in the macula is of importance in that it also occurs in Bright's disease and in syphilitic retinitis, hence it is not pathognomonic of brain tumor. Optic neuritis is of no value as a localizing symptom. The size of the tumor has no influence on the degree of neuritis. The effect of operation on choked disc is to produce a lessening soon after and there is also an improvement in vision in the majority of cases. The appearance of total blindness is of some localizing value. At times there is a degeneration of ganglion cells in the retina causing alterations in the visual field which must not be mistaken as a sign of brain tumor. This is a point which has not received the attention that it deserves. As to the varieties of choked disc there are three: an elevation due to edema of the disc; elevation due to inflammation, and elevation the result of a blending of these two. Wernicke's symptom is of importance, but is the most difficult to elicit of any test used in connection with the eye. The best way to examine for this is to have the patient behind a lamp with a rather weak mirror throwing a light in his face. A strong or short focus mirror is then used to throw a beam of light in the eye. DR. DERGUM said that for astereognosis to have a localizing value in cerebral tumors sensation must be preserved. If cortical it must be accompanied with motor or sensory phenomena, especially motor. He has seen Wernicke's symptom in one case when the patient was simply in a dark room and a candle was used.

NEW YORK.

Numerous persons were vaccinated in Oswego, N. Y., as a preventive of smallpox. The schools have been closed for this purpose.

Tuberculosis Bill.—The bill provides that the Commissioner of Agriculture instead of the State Board of Health shall have jurisdiction over domestic animals affected with tuberculosis, and further provides for the appointment of a State Appraiser of condemned cattle. The bill carries with it an appropriation of \$10,000. The committee decided to report the bill favorably.

State Medical Society.—The following resolution was adopted by the Medical Society of the State of New York: *Resolved*, That the Medical Society of the State of New York heartily endorses the report of the Tenement house Committee appointed by Governor Roosevelt, and urgently request, the legislature to adopt its recommendations regarding the improved housing of the poor, and the further control of the spread of infectious diseases.

Woman's Medical Association of New York City.—The Alumni Association of the Woman's Medical College of the New York Infirmary for Women and Children, has undergone certain changes. It was deemed advisable to make the society a living force by adopting its present more comprehensive name, and making women physicians, graduates of regular schools at home and abroad, eligible to active membership. The president of the Association is Dr. Elizabeth M. Cushier, and the secretary Dr. Evelyn Garrigues.

New Bill Defining Practice of Medicine.—The following bill is under consideration in New York State: "Any person shall be regarded as practising medicine within the meaning of this act who shall prescribe, direct, recommend, or advise, for the use of any other person, any remedy or agent whatsoever, whether with or without

the use of any medicine, drug, instrument, or other appliance, for the treatment, relief, or cure of any wound, fracture, or bodily injury, infirmity, physical or mental, or other defect or disease. This article shall not be construed as prohibiting the service of any person in an emergency, or the domestic administration of family remedies."

NEW ENGLAND.

Dr. Charles W. Stevens died suddenly, January 24, 1901, at his home, in Charlestown, aged 64. Dr. Stevens was born in Marlow, N. H., his father having been a distinguished surgeon, prepared for college at Wilbraham Academy, and was graduated at Harvard in the class of 1860. He went abroad in 1861 and began the study of medicine in London, at the same time teaching school. He came home before completing his studies and took his M.D. from Harvard in 1870. He at once located in Charlestown and remained there until his death. He served as city physician in 1872, and was at one time surgeon to the Wilson & Furness line of steamers. Dr. Stevens compiled the first book of college songs ever published in this country and was the author of many works.

CHICAGO AND WESTERN STATES.

For a State Hospital.—A bill has been introduced into the Senate of Missouri for the erection of a State hospital to cost \$1,000,000.

Smallpox in Iowa.—Forty cases of smallpox have been reported in various parts of the State notwithstanding every possible precaution.

Smallpox in Chicago.—A requisition has been made by the Health Department for 8 more men, on account of the prevalence of smallpox.

Dr. S. J. Quint, formerly resident physician of the California Hospital, has been appointed instructor of materia medica in the medical department U. S. C.

Appointment.—Dr. J. H. Davisson, Dr. Charles F. Taggart, Dr. J. W. Trueworthy, and Dr. C. W. Bryson have been appointed members of the Los Angeles Board of Health.

Hospital for Tuberculosis.—Treasurer Edward G. Uhlein of the citizens' committee for the erection of a hospital for the treatment of consumptives, has issued a report for January, showing that \$454 has been donated during the month. The amount now on hand for the undertaking is \$20,067.

Officers Chosen.—At the annual meeting of the Medical Society of City Hospital Alumni, St. Louis, the following officers were elected for the ensuing year: President, Dr. Norville Wallace Sharpe; vice-president, Dr. Francis L. Reder; secretary, Dr. John Green, Jr.; treasurer, Dr. Horace W. Soper.

Dr. Henry J. Herrick, a widely known physician and surgeon, died at Cleveland, Ohio. He was for many years professor of the medical department of the Western Reserve University. He was a member of the Loyal Legion, and served as a surgeon-general of the Ohio national guard during Governor Foraker's administration.

Fox River Valley Medical Society.—The annual meeting of the Fox River Valley Medical Society, of Green Bay, Wis., was held January 22, about 50 members being present. President L. O. Oviatt, of Oshkosh, presided, and Dr. J. S. Reeve, of Appleton, acted as secretary. Dr. W. A. Slaughter, of Green Bay, was elected president of the society; Dr. A. M. Kiersten, of Depere, first vice-president; Dr. C. E. Boyd, of Kaukauna, second vice-president; Dr. S. J. Reeve, of Appleton, secretary and treasurer; Dr. H. B. Tanner, of Kaukauna, censor. It was voted to hold the next annual meeting in Green Bay. The quarterly meetings were decided upon as follows: Waupaca in July, Neenah in April, and Oshkosh in October.

SOUTHERN STATES.

Smallpox in the University of Virginia.—It is stated that there are 4 cases of varioloid and 2 cases of smallpox in the infirmary.

Smallpox in Virginia.—Smallpox has developed near Ewing, Va. Nine cases have developed in one family, and the community has been placed in quarantine.

The College of Physicians and Surgeons of Baltimore has established a Pasteur Department for the preventive treatment of hydrophobia, at the Baltimore City Hospital.

Pension Board.—The following physicians have been appointed on the new Pension Board for Baltimore City: Drs. A. Trego Shertzer, fleet surgeon United States Naval Veterans, president; Henry S. Jarrett, of Towson, secretary; and Chauncey T. Scudder, treasurer.

Children's Hospital Board.—At the annual meeting of the incorporators of the Children's Hospital at Washington, January 21, the following were elected members of the board of directors: Landon W. Burchell, Clement W. Howard, S. W. Woodward, H. L. Biscoe, Gustav Lansburgh, T. N. McAboy, J. William Henry and Joseph E. Willard. The board of directors elected officers as follows: F. L. Moore, president; S. H. Kauffmann, vice-president; Dr. W. P. Young, secretary.

Richmond (Va.) News.—On the first of the month there was held a meeting for organization of the Ophthalmologic and Otologic Section as a branch of the Richmond Academy of Medicine and Surgery. It is composed of the members of the profession practising only on the eye, ear, and throat. The meetings will be held once a month at the different members' houses, the chairman of the meeting to be the entertainer of the evening. Dr. W. J. Mercer was elected permanent secretary.

MISCELLANY.

Hospital for Army Nurses.—A bill has been introduced some time ago and is again being revised regarding the erection of a hospital for army nurses.

Smallpox Epidemic.—It is stated that Dr. John B. Fulton, secretary of the Maryland State Board of Health, regards smallpox as epidemic in the whole United States.

To Establish Leper Colony.—Major Maus of the Surgeons' Department; Captain Ahern, chief of the Forestry Bureau, and Captain Horton, assistant Chief Quartermaster, sailed, on January 26, on board the *Alava*, from Manila, to complete the inspection of certain of the southern islands and recommend sites for leper and penal colonies.

Obituary.—DR. H. L. STICKEL, of York County, Pa., at Harrisburg, January 24, aged 48 years and 7 months.—DR. J. STUART LEECH, of Downingtown, Pa., January 23.—DR. R. E. BEACH, of Vandalia, Ill., on January 23.—DR. ROBERT GRAHAM at Pittsburg, Pa., January 19, aged 79.—DR. GRAFTON M. BOSLEY, of Lutherville, Md., at Baltimore, Md., January 25, 1901, aged 76 years.—DR. ERSKINE E. HAMILTON, at Springfield, Mass., January 22, 1901, aged 35 years.—DR. A. G. PRIEST, at Shelbyville, Mo., January 24, 1901, aged 72 years.—DR. T. S. DAVIS, at Wesson, La., January 23, 1901, aged 45 years.—DR. W. L. SIMPSON, at New York, January 26, 1901, aged 38 years.—DR. H. D. REARDON, at Elmira, N. Y., January 27, 1901.—DR. FREDERICK S. NEILSON, aged 37, at New Market, N. J., January 27, 1901.—DR. EDWARD J. MARSHALL, aged 60 years, at West Chester, Pa., January 28, 1901.—DR. W. J. HARRIS, aged 60 years, at Beatrice, Neb., January 26, 1901.

Hospital Corps Exercises at Manila.—A correspondent at Manila under date of December 7 describes the exercises attending the graduation of the second class of the hospital corps company of instruction. The event took place in Manila on December 4 in Hospital No. 2, of which Major John S. Kulp, surgeon, is in charge. That officer in his address said:

"On behalf of the officers of Hospital 3 I am glad to welcome you this morning, and to extend a cordial invitation to all to visit our company of instruction, hospital and camp. Without venturing to occupy the time of those who are so much better qualified to speak, I beg the privilege of a word in answer to a question asked a few minutes ago. What is the hospital corps? Wherever our flag floats over a garrison, from Fort St. Michaels to our own Bangao, we find men of the hospital corps, which numbers about 550 non-

commissioned officers, and over 3,500 men. The reason that one does not hear about them is because they are usually at work, and their work is very multifarious. First of all the private must be a good nurse, and we have yet to hear, so far as the hospital corps is concerned, of a patient pinning a note to his bed with the legend 'too sick to be nursed today.' In addition this man must be a soldier, for his work often takes him under the fire of the enemy, and a Mauser bullet is no respecter of persons. Then he must have a knowledge of pharmacy, must be something of a clerk in order to make out reports, must be a fairly good cook or he will find himself unpopular with his comrades and in short must be able to fill any place in hospital or camp. In most military hospitals, as in this institution, every position is filled by men of the hospital corps. But, I am asked, what is the need of military discipline? When in a crowded ward a case of cholera or plague develops, it is upon the strict obedience and attention to duty of the men of the hospital corps that the salvation of the surrounding city depends. When in the operating room a sudden emergency arises, it is upon their instant and unquestioning obedience that the life of the patient depends. And it is the soldier of the hospital corps who, through the long hours of the night, watches by the bedside under orders, for the symptom that he knows is but the surface play of the danger beneath. And so we think that the highest form of discipline is none too strict for those who at any time may be called upon to stand sentinel over the lives of our friends."

He was followed by Lieutenant William J. Lyster, assistant surgeon, commanding company instruction, and by Colonel Charles R. Greenleaf, chief surgeon of the division of the Philippines. The audience then joined in singing "The Battle Hymn of the Republic," the music of which was composed by a brother of Colonel Greenleaf, who also wrote the original words of "John Brown's Body." Other demonstrations followed by the class, showing the means used for the resuscitation of apparently drowned persons; the various manners of carrying injured men by single bearers and the final feat, which showed that a corps man, in addition to his multifarious duties, is required to be an athlete of no mean order. Six men, including the four litter bearers, took a litter with a patient on it over an obstacle more than eight feet above the floor, and that without disturbing the patient in any way. General MacArthur then presented the certificates to the class. The general had prepared to make an address to the men, but owing to a misunderstanding, it was cut out.

The graduates with their general averages, are as follows: Robert S. Ferguson, 91.5; Samuel B. Price, 89.7; William C. Hill, 87.2; Frank J. Foy, 87; Gordon F. Lyon, 85.3; Claude B. Bredford, 84.8; Arthur F. Wolf, 82.5; Edgar R. Hurst, 80.3; Michael J. Dorgan, 77.2; Ira L. Mather, 74.8; William Van R. Jenner, 73.3; Mayhew Elliot, 72.5; William D. McCary, 71.5; Herman A. P. Zybalski, 70.8; David M. Long, 70.2; Rudolf V. Steiner, 67.8; Charles A. Batchelder, 67.6; Raleigh Sebree, 67.4. Prizes and honors were as follows: For the best general average, Robert S. Ferguson, honorable mention, Samuel B. Price; best drilled man, Henry C. Leatherman, honorable mention, Claude Bredford; best examination in elementary anatomy and physiology, Samuel B. Price, honorable mention, William Van R. Jenner.

Changes in the Medical Corps of the U. S. Army, for the week ended January 26, 1901:

MULLINS, THOMAS K., acting assistant surgeon, is granted leave of absence for 1 month.
The following named acting assistant surgeons will stand relieved from temporary duty at their present stations on the day of the sailing of the "Grant," and will report on that transport for temporary duty during the voyage: ABRAHAM D. WILLIAMS, Camp of Casuals, Presidio; WALTER B. CHESTER, and CARROLL D. BUCK, Army General Hospital, Presidio.
BAILEY, GUY C., acting assistant surgeon, is granted leave of absence for 1 month.
The following named acting assistant surgeons will stand relieved from duty at their present stations on the day of sailing for the Philippine Islands of the Army transport "Grant," and assigned to temporary duty with troops on that transport: upon arrival at Manila they will report to the commanding general, division of the Philippines, for assignment to duty: HENRY D. BROWN, JOSEPH W. REDDY, JOSEPH PETTYJOHN, THEODORE H. WEISENBERG, and JOHN H. ALLEN; JOHN S. HILL, COMPTON WILSON, Presidio; LAWRENCE McCLEON, ALFRED T. SHORT, FREDERICK W. RICHARDSON, ROBERT S. SPILLMAN, Army General Hospital, Presidio.
WILLIAMS, ALLIE W., acting assistant surgeon, will upon expiration of present leave proceed to Governor's Island for assignment to duty at Fort Columbus.
DISNEY, FRANK A. E., acting assistant surgeon, now in Washington, D. C., will proceed to San Francisco, Cal., and report for temporary duty at the General Hospital, Presidio.

WILLIAMS, ALLIE W., acting assistant surgeon, is granted leave of absence for 1 month.

REED, Major WALTER, surgeon, will, upon the adjournment of the Pan-American Medical Congress at Havana, Cuba, proceed to Washington, D. C., and report to the Surgeon-General of the Army for the purpose of continuing his investigations at the Army Medical Museum with reference to the cause and prevention of yellow fever.

RICHARDS, First Lieutenant WILLIAM E., resignation of, is accepted to take effect February 3.

BELT, HARRY D., acting assistant surgeon, is granted leave of absence for 2 months, without pay.

TRUAX, JESSE P., acting assistant surgeon, now en route to Fort Casey, is relieved from the further operation of the order which directs him to proceed to Fort Casey, and he will report at Fort Flagler for duty, relieving Acting Assistant Surgeon William M. Hendrickson.

HENDRICKSON, WILLIAM M., acting assistant surgeon, will proceed to Fort Casey for duty.

HARRIS, HERBERT I., acting assistant surgeon, is detailed as a member of the board of officers appointed January 15 to meet at St. Paul, Minn., for the examination of officers for promotion, vice Lieutenant Colonel Calvin DeWitt, deputy surgeon-general, relieved.

BISPHAM, First Lieutenant WILLIAM N., assistant surgeon, is relieved from duty at Columbia Barracks, Cuba, and will proceed to No. 21 Fifth street, Vedado., Havana, Cuba, reporting to the commanding officer, Second Artillery, for duty at batteries Nos. 3 and 4, and the regimental hospital, Vedado, relieving Acting Assistant Surgeon P. C. Field.

FIELD, P. C., acting assistant surgeon, will proceed to Columbia Barracks, Cuba, for duty.

CARR, Major LAWRENCE C., surgeon, will upon the expiration of the leave granted him December 17, proceed to Havana, Cuba, and report to the commanding general, department of Cuba, for assignment to duty.

MORSE, ARTHUR W., acting assistant surgeon, now at Odell, Ill., will proceed to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty.

CONN, FREDERICK A. W., acting assistant surgeon, is relieved from duty in the department of Cuba, and will proceed to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

NEALE, JOHN S., hospital steward, now at Columbia Barracks, Cuba, will be relieved from further duty at that post, February 10, and sent to Washington, D. C., reporting to Major John Van Horn, surgeon, medical supply officer, for duty in the pathological laboratory at the Army Medical Museum.

The following named officers will report to Colonel Alfred A. Woodhull, assistant surgeon-general, president of the examining board at the Army Medical Museum building, Washington, D. C., for examination for promotion: Captains CHARLES M. GANNETT, JEFFERSON R. KEAN, HENRY L. RAYMOND, EDWARD R. MORRIS, LEONARD WOOD, JEFFERSON E. PENDLETON, CHARLES E. WOODBRUFF, assistant surgeons.

Changes in the Medical Corps of the U. S. Navy, for the week ended January 26, 1901:

FISKE, G. N., assistant surgeon, detached from the "Wheeling" and ordered to the "Mohican" when the former is put out of commission.
SHIFFERT, H. C., assistant surgeon, appointed assistant surgeon from December 26, 1900.
BERTOLETTE, D. N., medical inspector, detached from the Medical Examining Board, Washington, and ordered home, January 31.
RUSSELL, A. C. H., surgeon, ordered to Washington, for duty as a member of the Medical Examining Board, January 31.
RUSH, W. H., surgeon, ordered to the Pensacola Naval Station for recruiting and other duty.
SMITH, R. K., passed assistant surgeon, detached from the "Pensacola," February 2.
STONE, M. V., assistant surgeon, detached from the "Solace" and ordered to the "Isla de Luzon."
HASS, H. H., assistant surgeon, detached from the "Isla de Luzon" and ordered to the "Solace."

Changes in the U. S. Marine-Hospital Service, for the week ended January 24, 1901:

PURVIANCE, GEORGE E., surgeon, granted leave of absence for 2 days, January 18, 1901.
WILLIAM, L. L., surgeon, granted leave of absence for 3 days, January 21, 1901.
BEAN, L. C., acting assistant surgeon, granted leave of absence for 3 days from January 18. January 17, 1901.
CRANE, R. C., acting assistant surgeon, granted 7 days' extension of leave of absence. January 22, 1901.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended January 26, 1901:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.

foreign News and Notes.

GREAT BRITAIN.

Indian Medical Association.—The twenty-second meeting of the council of the Indian Medical Association was held December 15, at Calcutta.

Smallpox in Glasgow.—An epidemic of smallpox is raging in Glasgow. Twenty-nine cases were reported on January 26, and 100 cases in the hospitals.

Dr. John White Aldred, of Altrincham, is reported to have died of typhoid fever at Kroonstadt, South Africa. Dr. Aldred was a distinguished student at Owens College.

Plague among Troops.—According to the *Petit Bleu*, bubonic plague is raging among the British troops in Cape Colony, and many deaths that are attributed to enteric fever and dysentery are due to plague.

Enteric Fever in Ceylon.—On account of the increase of enteric fever in the Boer camp in Ceylon, the government of India has ordered one medical officer of the rank of captain to proceed there; another one will shortly follow him.

Prize for X-ray Tube.—The Council of the Röntgen Society at London announces that the president has placed at its disposal a gold medal to be awarded to the maker of the best practical x-ray tube for both photographic and screen work.

Sheffield Bacteriological Laboratory.—At a recent meeting of the Sheffield Medico Chirurgical Society, Dr. Robertson read a paper on the work done at the bacteriological laboratory in connection with University College since its establishment. Courses of instruction for medical students and post-graduate courses, have been held. During the past 18 months 1,605 swabs have been examined from patients suspected to be suffering from diphtheria, nearly 500 specimens of blood have been examined for serum reaction, and 663 specimens of sputum have been examined for tubercles.

Sir W. H. Farrington, Bart., M.D.—Sir William Hicks Farrington, Bart., M.D., who died suddenly on January 5, at Penshurst Kent, was the eldest surviving son of Sir Anthony Farrington, Bart., of Ottery St. Mary. He began his medical education at St. Bartholomew's Hospital in 1856, became a member of the Royal College of Surgeons, and Licentiate of the Society of Apothecaries in 1859-60, and graduated at St. Andrew's in 1862. He held the appointment of resident accoucheur at St. Bartholomew's under Dr. West, and subsequently he became resident medical officer at the London Fever Hospital. On resigning this post he was appointed medical officer to Her Majesty's convict establishment at Gibraltar. Returning to England in 1866 he settled at Penshurst in Kent, taking the practice of Dr. J. H. Baller, who was retiring from active life. In 1870 he married the youngest daughter of the late Mr. Alexander Glendinning, of Redleaf, Kent, who survives him.

CONTINENTAL EUROPE.

A clinical service devoted to tropical diseases has been instituted at the Medical College of Algiers. Prof. M. Brault has been appointed to take charge of the service.

Medical Club of Paris.—The following officers were elected for 1901: President, M. Peyrot; vice-presidents, M. M. Chevallereau and M. Hallopeau; secretaries, M. M. Doléris and Lefèvre; treasurer, M. Desnos; librarian, M. Chassevant.

Appointments.—BRUSSELS: Dr. Bayet was appointed professor of the dermatological clinic, and Dr. Chevel professor of the laryngological clinic.—WÜRZBURG: Dr. Friedrich Schenck has succeeded Professor Kossel as ordinary professor of physiology at the University of Marburg.—HEIDELBERG: Professor Albrecht Kossel was appointed ordinary professor of physiology as well as director of the physiological laboratory at the University of Heidelberg.

A Case of Calcareous Infiltration of the Liver.—E. Mihel (*Srpski arhiv za celokupno lekarstvo* 1900, No. 10 (Serbisch) in performing an autopsy upon a boy aged 17 years, who had suffered from chronic pulmonary tuberculosis with cavities and an old parenchymatous nephritis with acute hemorrhagic exacerbation, noticed that the liver grated under the knife. The organ was of a normal shape, somewhat diminished in size, the tissue showing considerable vascularization and markings resembling a nutmeg-liver. Upon closer observation minute grayish yellow ramifications were noticed which felt rough to the palpating finger. Microscopical examination showed that these arborescent structures represented an extensive impregnation of the liver-parenchyma with lime salts. The application of a 5% solution of hydrochloric acid caused the calcifications to become invisible under the microscope, and as they were seen to disappear without the formation of gas bubbles, it was deduced that the salts consisted of phosphate of calcium. The calcareous impregnation of the liver-cells was most marked around the central veins. At those areas where the salts had been removed by the acid it was plainly seen that the parenchyma had been replaced by fatty degeneration. The author could find no similar case in literature where a nutmeg liver followed chronic pulmonary tuberculosis. [M. R. D.]

The Latest Literature.

British Medical Journal.

January 12, 1901. [No. 2089]

1. Observations on Wind Exposure and Phthisis. WILLIAM GORDON.
2. Jaundice in Typhoid Fever. GEORGE OGILVIE.
3. Influenza and the Nervous System. JAMES CARSLAW.
4. The Detection of Arsenic in Beer and Brewing Material. SHERIDAN DELEPINE.
5. Note on the Value of Inoculation Against Enteric Fever. HENRY CAYLEY.

1.—After a study of the statistics and the death-rate, Gordon concludes that the distribution of the phthisis death-rate in the rural sanitary districts of Devon is due to some other cause than general sanitation. On the other hand, a comparison of a diagram of the deaths from tuberculosis of the lungs and a diagram indicating rain and all suggests a kind of rough correspondence. The town with the highest death-rate has the greatest rainfall and that with the lowest death-rate has the lowest rainfall. The correspondence is by no means complete, however, and the author concludes that probably, for Devonshire generally, the paramount influence that determines a higher or a lower rate of **mortality from tuberculosis of the lungs** is the degree of exposure to or shelter from the west and the southwest winds. [J.M.S.]

2.—Ogilvie reports 4 cases in which **jaundice** complicated **typhoid fever**. In the first, the patient was a young woman, aged 22 years. The jaundice was present from the beginning of the disease and began to disappear when the temperature began to fall. It had not quite cleared up 8 weeks after the onset when the patient was sent to a convalescent home. The second patient was a man, aged 30 years. The jaundice appeared on the fourth day after admission to the hospital, or was about the end of the first week of the disease. It gradually disappeared as the temperature fell, and lasted nearly throughout the whole of the disease, about 6 weeks. The third patient was a man, 30 years old. In this patient the jaundice preceded the advent of the attack of typhoid fever by about 4 weeks and lasted for about 3 weeks of the course of the disease. The case is one of typhoid fever in a jaundiced patient and the jaundice cannot be thought to be a symptom of the typhoid. The attack was probably of catarrhal origin, although it might have been due to some toxic process dependent on dysentery. The fourth patient was a girl, aged 16 years, who passed a lubricoid worm during the attack of typhoid. The worm had evidently obstructed the common bile duct and had caused the jaundice. After a study of the reported cases in the literature, the author concludes that the frequency of jaundice in typhoid fever is between 1% and 1½%. This would indicate that jaundice is not so rare and so fatal a complication of typhoid fever as has been frequently presumed. It is a most unusual occurrence for jaundice to appear at the onset of the disease, to last through its whole course, and to disappear with the falling of the temperature, and yet to lead to no serious results. In fact, similar occurrences are so rare that they may lead to doubts as to the correctness of the diagnosis of typhoid fever. The cases reported by the author, however, seem to be true typhoid fever as indicated by the presence of the agglutinating reaction of the blood-serum in addition to the classical symptoms of the disease. Clinical and pathologic evidence seem to prove that catarrhal jaundice in typhoid fever, so far from being the rule, is an exceedingly rare occurrence. While in the first 2 cases reported in the paper catarrhal jaundice can be excluded, it is more difficult to come to a conclusion as to the causation of the symptom. It is possible that there is some direct action of the specific microorganism of typhoid fever on the liver or the bile channels, as suggested by DaCosta, that accounts for the occurrence of the jaundice in these cases. [J.M.S.]

3.—Carslaw reports 4 cases that illustrate the influence of **influenza upon the nervous system**. The 4 patients suffered from acute meningitis. This meningitis may have been the principal incident of the attack of influenza, or, on the other hand, the infection may have been a mixed one,

and the attack of influenza may have simply paved the way for the entrance of other toxic agents as well as for the bacillus of Pfeiffer. Although 3 of the cases were fatal, a post-mortem examination was permitted on only 1, and in that case the examination was limited by the friends to the contents of the skull. In this case the meningitis was found to have been of a very acute type. Its bacteriology, however, was not very satisfactorily made out. Diplococci of comparatively large size were found in the films prepared at the post-mortem, but the attempt to make cultures from the purulent effusion failed. It is possible that the influenza bacillus was present in addition to the diplococcus, both being difficult to cultivate except in specially prepared media. Of course, the infection may have been a pure diplococcic invasion from the respiratory tract, the catarrhal involvement of which would have favored such an extension whether the primary disease was influenza or not. There was in this case an alveolar sarcoma of the round-celled type involving the pituitary body. The patient had always been considered a healthy, strong, and well-developed young man, and had presented none of the symptoms of akromegaly. The only symptom that could be considered to bear any relation to this tumor was occasional attacks of pain in the head, of short duration, which the patient had experienced for about 6 months before his illness. The other fatal cases resembled each other very closely. In each the illness lasted about a week and occurred in strong and healthy young men, not the subjects of tuberculous disease. The first symptoms in each case were those of influenza, and the patients passed somewhat suddenly into a state of unconsciousness from which they never rallied. The patient who recovered was a boy, aged 9 years, who was probably suffering from acute inflammation of the cerebral meninges and possibly, also, of the spinal meninges. The onset of the illness was sudden and the meningeal symptoms were early and severe, and, in addition to other characteristic symptoms, the patient had a very typical herpes labialis. In all these cases the illness occurred in healthy subjects and at a time when influenza was present in the neighborhood. Some of the patients had early catarrhal symptoms that were considered by their medical advisers to be of an influenzal nature. In all severe headache was prominent, and grave cerebral symptoms developed with alarming rapidity and with no apparent cause in the ears or elsewhere. They were all characterized by very restless delirium and, in general, little or no paresis of limb or ocular muscle to indicate any important localization. Probably the meningitis was more vertical than basal, although, in the case that came to the autopsy table, the exudation was very well marked both at the base and on the convexity. In that case, however, there had been localizing symptoms. The author adds a summary of a very marked case of postinfluenzal multiple neuritis. The patient's illness corresponded with the usual features of alcoholic peripheral neuritis and at first there was a suspicion that the disease might be of that nature. This etiologic factor was excluded, however, and, although the patient had had a distinct attack of influenza, she persevered in her work so that there was more likelihood of a complication, such as neuritis, developing. [J.M.S.]

4.—It is a fact of common knowledge among chemists and biologists that arsenic is one of the most widely-distributed substances. It is frequently associated with other metals and sulphur in various mineral products. Many soils contain arsenic; vegetables growing in such soils may contain traces of that body, which is more abundant in their seeds. The soil may also be rendered arsenical artificially, as when various chemical products are thrown upon the ground. Contamination of water may occur under those circumstances. Some valuable mineral waters, more especially the ferruginous waters, contain minute quantities of the poison, owing to their passage through arseniferous strata. It has also been found in sea-water. It has even been lately asserted that arsenic is a normal constituent of the human body. Taking these things into consideration, Delépine thought that the mere detection of traces of **arsenic** would not be sufficient to prove that any sample of **beer** was actually dangerous to health. No authoritative statement could be found showing that pure beer should be absolutely free from arsenic; on the other hand, it was quite conceivable, on the ground of general knowledge, that minute traces of arsenic might occur in beer even prepared from the best

material, and that this must have, in fact, occurred at all times since beer began to be brewed from malt and hops. After preliminary study, the author felt justified in considering that any beer containing about 0.8 grain of arsenious acid per gallon—that is, 1 part of As_2O_3 per 875,000 parts of beer—should be condemned. By conducting Reinsch's test with care, he found that it was easy to detect the presence of arsenic in 100 cc., and even in as little as 20 cc., of some of the suspected beers. On the other hand, no distinct trace of arsenic could be found in as much as 200 cc. of beer brewed in Bavaria, where the use of malt substitutes is prohibited by law. After further careful study, it was found that a sublimate composed of small but clear crystals of arsenious acid could be obtained from the solution containing 1 part per million without any previous concentration of the beer. This amount of arsenic is higher than that which we have so far found in beers brewed from ordinary malt and hops. On the other hand, this quantity is considerably below that found in beers brewed from arsenical glucose. It will be understood that the standard adopted for the present is purely artificial, and that by Reinsch's method it would be possible to fix a much more stringent standard if necessary, for there would be no difficulty in discovering by this test 1 part in 5,000,000, in 10,000,000, or even less, by increasing the quantity of, or concentrating the fluid under examination. Supposing that an arsenical beer was entirely brewed from malt, the malt should contain at least 4 times more arsenic than the beer prepared with it, since the proportion of malt used may be said roughly to be $\frac{1}{4}$ of the total amount of beer produced from it. We have not, however, found yet any sample of malt containing more than a small fraction of the arsenic present in arsenical beer to which cases of poisoning had been traced. With regard to the glucose and invert sugar, the amount of arsenic found in some samples was more than sufficient to account for the dangerous contamination of the beer. The sulfuric acid used in the factory from which all the arsenical glucose examined came contained so much arsenic that it was actually saturated. A deposit of arsenious acid, or some arsenical compound formed in the presence of sulfuric acid, was actually found at the bottom of the bottle containing the acid sent for examination. By a modification of Reinsch's method described in the paper, the author found that the amount of arsenic acid in one sample of H_2SO_4 was about 2%. [J.M.S.]

5.—Cayley gives the results of the **inoculation** of the members of the staff and establishment of the Scottish National Red Cross Hospital serving in South Africa **against typhoid fever**. The first section of the hospital, consisting of 61 persons, left Southampton on April 21, 1900. During the voyage out all except 4 of the personnel were inoculated twice at an interval of about 10 days. The injections were all made in the flank and were followed in from 2 to 10 hours by marked symptoms, both local and constitutional, that lasted for from 2 to 5 days. In many cases the symptoms were as severe after the second as after the first inoculation. This would seem to show that it takes more than 10 days before any immunity is established. Two of the 7 nurses were not inoculated, because they had already had attacks of typhoid fever, and 2 of the orderlies were only inoculated once. Out of about 300 troops on board, chiefly volunteers and militia, nearly 100 were inoculated. As soon as the hospital reached the Cape it was sent to Kroonstadt, in the Orange River Colony, and remained there as a stationary hospital until the middle of October. During this period there were always many cases of typhoid fever under treatment in the hospital. Furthermore, some of the medical officers and student orderlies had charge of the Kroonstadt Hotel temporary hospital, which was crowded with enteric cases, and the nursing sisters did duty for 3 weeks in the military hospitals at Bloemfontein in May and June when typhoid was at its worst. There was not a single case of typhoid fever among the personnel of this first section of the hospital. The second section of the hospital, 82 in all, left Southampton in May, 1900. Nearly all were inoculated on board ship, but many were inoculated but once. The material for the inoculation had been on board for some time and was not so fresh as in the first instance. Of this second section, one nurse had typhoid at Kroonstadt. She was the only one out of 36 nurses who had typhoid and she was also the only one who had not been inoculated; 5 orderlies of the second section had typhoid, of whom 2 died. Of these 5, 2 had been

inoculated once and 3 had not been inoculated. Of the 2 that died 1 had been inoculated once and 1 had not been inoculated. A third section of the hospital consisting of 20 people went out in July; they were all inoculated and none of them had typhoid fever. At the end of August, the blood of a number of the staff and establishment was examined for the serum reaction. The blood of 23 of the members of the first section, who had been inoculated 4 months before, was examined and of these 21 gave a good reaction and 2 gave a slight reaction, the orderlies who had been inoculated but once. The blood from the 22 members of the second section was tested, these had been inoculated for 3 months. Of these, 11 gave no reaction, 9 gave a very slight reaction, and only 2 gave a good reaction. It would appear from the above that the members of the first section were much more fully protected against typhoid than the members of the second section. It is not quite clear why the inoculations of the first section were so much more effective than those of the second section. Probably the freshness of the material had an influence; and the author thinks that the dose for each individual was more carefully measured for the first than for the second section. So far as could be learned, the members of the first section suffered more severely at the time from both local and constitutional disturbances. The results above given seem to be very strong evidence in favor of the protective power of anti-typhoid inoculations, when they are very carefully performed, and they point to the necessity for 2 inoculations at suitable intervals. During the period of 5 months that the hospital was stationed at Kroonstadt, there were 92 admissions for enteric fever with 11 deaths. Of the 92 cases, 15 said that they had been inoculated. Of the 11 fatal cases, 1 occurred in a patient who had been inoculated once. The author fears that any statistics bearing on the question of the efficacy of the inoculations derived from the hospitals in South Africa, will not be of great value. At the same time he feels convinced that the attacks of typhoid fever were, as a rule, much milder in the inoculated than in the noninoculated, and that the duration of the disease in the inoculated was shorter. [J.M.S.]

8. The Relation of the Bowel Lesion of Typhoid Fever to the General Symptoms of the Disease. T. J. MACLAGAN.
9. Reflections on Therapeutics. HARRY CAMPBELL.

1.—Freyer thinks that the term "senile" should not be applied to **enlargement** of the prostate gland, as it is not dependent upon senility. About 33% of men past 55 years have enlarged prostates, but only about 5% ever suffer from symptoms. When the hypertrophy involves the whole gland and the enlargement is uniform, symptoms are not usually present. Enlargement of the middle lobe gives rise to most trouble. Sometimes the overgrowth, when examined histologically, resembles a fibromyoma, but more often the hypertrophy involves the glandular tissue largely, and the growth would seem to be adenomatous, and this is always true in the beginning. The so-called "prostatic tumors," localized hypertrophies, may occur anywhere in the gland, and as they grow, project into the bladder, and have only attachment by small pedicles. The length and course of the urethra may be greatly altered, according to the position of

the hypertrophy. The changes in the bladder-wall are described with the formation of a postprostatic pouch, and the extension of infection from foul urine up the ureter to the kidneys. Constant straining at micturition may produce prolapse of the rectum or hemorrhoids. Freyer inclines to the view that the hypertrophy is analogous to fibroid disease of the uterus, rather than that it is due to a general arterial sclerosis. He describes the symptoms produced by enlargement of the different lobes of the prostate. He advises that when the amount of residual urine is large, as can be determined by palpation and rectal examination, that the whole amount should not be drawn at the first examination. He urges a thorough examination of the prostate by the finger in the rectum, first in the recumbent position and then in the knee-chest position, determining its shape, consistence, degree of tenderness, etc. Examination with the sound and cystoscope will decide the degree of hypertrophy of the middle lobe. Patient should remain in bed for a day. [J.H.G.]

2.—Cave, in an article on **pneumococcic arthritis** states that while the condition is a very uncommon one, many cases escape detection on account of the lack of bacteriological examination. He gives a report of a case of his own and 30 collected from literature. The history of his case is as follows: The patient, a man aged 51 years, follows the occupation of farming. When he was first seen by Dr. Cave the signs of a pneumonia involving the right base were elicited. His illness had existed for 11 days. On the sixth day of the disease his temperature fell by crises, but only to rise again accompanied by signs of consolidation of the left base. When seen by Dr. Cave the patient was in a moribund state and therefore too ill to be carefully examined. At this time it was found that his left shoulder was swollen, red, and edematous. It was ascertained that this shoulder had been injured 5 days before in struggling during his delirium. Death occurred an hour after Dr. Cave's visit. From the shoulder-joint thick, greenish, creamy pus was obtained by aspiration. The pus contained pneumococci. Inoculations were made on agar and blood serum and cultures of the pneumococcus developed. In an analysis of the 31 cases, 23 terminated fatally and 28 were immediately associated with pneumonia. In only 2 cases did the arthritis precede the pneumonia. Three cases occurred without pneumonia. Pneumococcic arthritis is much more common in males than in females, and occurs especially in adult and in advanced life. The upper extremity is involved more frequently than the lower. In 27 of the cases suppuration developed, in 3 there was no pus formation, and 1 case was doubtful. The pneumococcus was demonstrated in 30 of the cases. Manifestations of widespread infection were observed in a number of cases; 6 were complicated with malignant endocarditis, 5 with pleurisy and empyema, 2 with pericarditis, 3 with nephritis, 6 with meningitis, and 1 with peritonitis. In some of the cases more than one serous membrane was involved at the same time. The specific microorganism is found in the fluid of the exudate embedded in some of the cells and upon the free surface of the exudate, but not in the deeper tissues of the joints. Permanent injury to the joint often follows this form of arthritis, but in some of the milder cases complete function is restored. Injury or previous disease of a joint predisposes to pneumococcic infection. He further states that experimental evidence gives abundant proof that the injection of the pneumococci into a joint in susceptible animals is almost always followed by suppurative arthritis. Subcutaneous injection is often followed by inflammation of a joint which has been previously irritated. If the injection be intravenous, arthritis is more apt to follow. If a rabbit be partially immunized to the pneumococcus and then a virulent culture injected, septicemia is not so liable to follow, but rather local involvement, especially arthritis. The clinical manifestations of pneumococcic arthritis vary. The local symptoms may be slight or intense; fever is as a rule high, and the diagnosis depends upon the finding of the specific microorganism in the affected joint, or upon the association with pneumonia or other pneumococcic forms of infection. The prognosis is always grave. As to the treatment, in the suppurative variety of arthritis, early incision, free drainage and rest of the part is recommended. When the effusion is serous or serofibrinous (as determined by aspiration) rest and compression are the important measures. The after-treatment consists in the use of hot-air baths, hydrotherapeutic measures, and massage. [F.J.K.]

3.—Griffin reports a case of **siriasis**. The patient, aged 25, an Englishman, and assistant engineer by occupation, had been in good health up to the time of the present illness. After working for some time in the boiler-room of the ship in which the temperature was 114° F., he developed siriasis. His pulse was as high as 160 per minute, his respiration 60 per minute, and his temperature 108.6° F. After a rather prolonged illness, he finally recovered. The early treatment consisted of ice-packs, cold sponging, and the administration of digitalis. Later, the treatment consisted principally of sponging, and the administration of quinin, calomel, ammonium bromid, and diaphoretics. [F.J.K.]

4.—Barnard describes a case of **dorsal luxation of first phalanx of little finger**, due to a blow on the back of the hand, which it was impossible to reduce by any form of manipulation, but which was readily replaced after division of the splenoid ligament through a small dorsal incision, after the manner described by Farabœuf for the reduction of the same dislocation of the thumb. He does not think that the slipping of the head of the metacarpal bone between the tendons offers the obstruction to reduction that was at one time supposed. He has produced and studied a number of artificial dislocations and concludes the subject thus: 1. That dislocation backwards of the first phalanx of the little finger is rarer than that of the index finger and much rarer than that of the thumb. 2. That, unlike the similar dislocation in the thumb, it is probably produced in most cases by violence applied to the dorsal surface of the head of the metacarpal bone. 3. That the 3 varieties—(a) incomplete dislocation; (b) the complete simple dislocation; and (c) the complete complex dislocation—so admirably described by Farabœuf in the case of the thumb—apply equally to the little finger. 4. That the incomplete dislocation is easily reduced by pushing the phalanx forward; the complete simple form by the method of manipulation suggested by Farabœuf; whilst the complete complex dislocation, the result of ill-directed manipulation, requires the simple operation suggested by Desault, Farabœuf and Hulke.

5.—Tubby notes that **Dupuytren's contraction** of the palmar fascia is more common in men than in women, that it usually comes on after 40 years of age, and that the patients often give a gouty history. Cause is unknown. He recommends the open method where the fascia is dissected outwardly, as preferable to the older method of subcutaneous division of the fascia. The **prognosis** in cases of **tendon division** in the hand, Tubby says, is dependent on 3 factors: first, the power of retraction; second, the amount of fixation of the tendon in its sheath, and, third, the character of the structures at the spot where division occurs, particularly as regards the circulation in these parts. [J.H.G.]

6.—MacLulich and Goodall report the case of a man who had lost his left forearm from traumatism when a boy, and who, at the age of 63 years, developed melancholia and died suddenly of angina pectoris. Examination of the brain showed but one lesion, a softening occupying the gray matter of the base of the right second frontal convolution where it joins the ascending frontal. The area presented signs of having wasted. It looked old, but there was no sclerosis. The subjacent white matter showed no change to the naked eye. The point of interest in the case is the possible relationship between the loss of the arm and this wasted area which was anterior to the portion of the brain supposed to control the forearm and hand. [J.H.G.]

8.—The relation of the **bowel-lesions of typhoid fever to the general symptoms** of the disease is discussed by MacLagan. He notes that fever is the most prominent symptom. He believes that the fever and other general manifestations in the course of this disease are not due to the local lesions, but to the great number of virulent bacilli which have found their way into the circulation. The chief action upon the tissues produced by the bacilli is the consumption of nitrogen and water. He further believes that the essential phenomena of the disease, such as increased elimination of urea, thirst, loss of appetite, wasting, etc., are dependent upon these two conditions, namely, the consumption of nitrogen and water by the contagium. The soda salts are eliminated in diminished quantity or they are retained, while the potash salts are more freely eliminated. The reason for this is that the soda salts are taken up by the bacilli, and the potash salts, which exist in the tissues, for reason of increased dis-

integration, are eliminated. When the glandular tissue, which forms the focus for the morbid process, is destroyed, the general manifestations of the disease come to an end. Recrudescence of the fever is explained as follows: Some of the intestinal lesions are involved late in the course of the disease, while others are undergoing healing. Relapses are explained in a similar way, namely, that the pathological progress in some lesions is greatly retarded. He states that the uneven distribution of the microorganisms in the blood may cause some of the lymphoid structures to escape infection. This may occur even after one or two relapses. The local disturbances are due to the multiplication of the bacilli in the lymphoid tissues of the intestine. The late symptoms in a severe case may be in part ascribed to a septic poisoning during the stage of sloughing and ulceration. At this time various forms of cocci are associated with the primary infection. This is especially likely to occur when gangrenous ulceration develops. [F.J.K.]

1. Gastroenterostomy by the Elastic Ligature. THEO. D. MCGRAW.
2. Cereals, Emulsions and Proteids in Infant Feeding. T. M. ROTCH.
3. I. Septicemia, Acute Bacteriemia; and Pyemia, Chronic Bacteriemia. II. The Indications for Hysterectomy and the Indications for Abdominal Section and Drainage in Puerperal Infection. H. J. BOLDT.
4. Observations on the Toxic Effects of Some Common Drugs. PHILIP F. HARVEY.
5. The Treatment of Influenza. W. H. THOMSON.

1.—McGraw has performed the operation of **gastroenterostomy by the elastic ligature** in 5 cases. Two of these patients died in collapse a few hours after the operation, 2 of the 3 others lived, one 15 days and the other 14 days after the operation, the one dying from starvation due to the anastomosis having been located too near the ileocecal valve, and the other from the formation of the "vicious circle." The third feels in perfect health, unconscious of the disease which must sooner or later end his life. The term "vicious circle" is applied by German surgeons to a condition sometimes occurring after gastroenterostomy, in which the food passes from the stomach into the afferent instead of the efferent limb of the intestine. It then fills the duodenum, soon to regurgitate and pass again into the stomach. The causes of this condition are not well understood. If not relieved it results in the death of the patient. McGraw emphasizes the necessity of a proper technic as regards: 1. The ligature. This should be a hard, round, smooth and strong rubber cord, at least 2 millimeters in diameter. 2. It must include in one loop all of the tissue which it is desirable to sever. 3. The cord must be drawn as firmly and tightly together as possible and fastened by a silk thread which is tied around them. 4. Before inserting the rubber ligature the viscera should be joined together by a row of Lembert sutures for a distance of 6 or 7 centimeters, and when the ligature has been tied a similar row in the front should complete the function. [W.A.N.D.]

2.—Rotch discusses the subject of **cereals, emulsions, and proteids in infant feeding**. He states that the addition of cereals to the milk is chiefly for one of two reasons: 1. That the resulting food should have a greater nutritive value from the administration of starch in addition to the chief elements constituting human milk, namely, fats, milk-sugar and proteids. 2. To aid in the digestion of proteids by acting in some mechanical way on the coagulum of the caseinogen, so as to render it finer and more closely to approximate the coagulum of human milk. In his experience with milk carefully modified in the laboratories he has many times met with a disturbance of the emulsion, but has not been able to see that it did any special harm, as only part of the emulsion, and a small part, is disturbed. The management of the proteids in an infant's food is important. The results of the experiments as to the coagulability of whey-mixtures are still *sub judice*, but so far as they

go they bear out the theoretic assumption that the coagula are very distinctly finer than in an ordinary modified milk of the same total proteids. The management of the coagulum depends on the management of the caseinogen, and the coagulum will be small and fine if the caseinogen is kept down to its proper relative proportion to the whey proteids. [W.A.N.D.]

3.—Boldt discusses the **indications for hysterectomy and the indications for abdominal section and drainage in puerperal infection**, whether due to septicemia—acute bacteriemia, or pyemia—chronic bacteriemia. He believes that it is impossible, with our present knowledge, to lay down absolute rules for the performance or omission of these operations. He suggests the following indications for hysterectomy, if it is evident that less heroic treatment is useless: 1. If, after a full-term delivery or an abortion, there are no conception-products in the uterus, and the patient has fever with exacerbations, chills, and a small and frequent pulse (120 to 140 or more), if careful observation should show that the infection comes from the uterus alone, that organ being enlarged, and relaxed in its consistency, if there is no evidence of peritonitis, the parametria being free of streptococci are found in the uterus, and especially if the blood shows the presence of pathogenic germs. 2. If there are decomposition-products in the uterus which cannot be removed satisfactorily *per vaginam*, if, on doing a cesarean section, the uterus is found septic, then an abdominal hysterectomy is indicated. Abdominal section with drainage is indicated in diffuse septic peritonitis when there is no evidence of an exudate in the pelvis. The adnexa are to be left undisturbed, unless there is some positive indication to do otherwise. [W.A.N.D.]

4.—Philip F. Harvey points to the growing tendency towards **greater conservatism in the treatment of chronic ailments by the use of drugs**, and there is less disposition to push certain medicinal substances beyond the point of tolerance. He details a case in which a patient suffering from a pustular acne declared that she was unable to take arsenic or mercury in any form. He gave her very minute doses of bichlorid of mercury and chlorid of arsenic. (He does not, however, state the doses.) The patient tolerated the treatment extremely well, and in 3 months was completely cured. He deprecates the use of **mercurials in the treatment of syphilitic infants**, it being established by observation that injurious effects may result, and it is extremely doubtful that mercury has any therapeutic value in syphilitic conditions in infancy. In general, Harvey believes that we should be cautious in administering drugs in heroic doses, and that the study of their action is necessary before we can say that the drug is not doing more harm than good. [T.L.C.]

5.—W. H. Thomson considers the **treatment of influenza**. He believes that **aconite** is one of the best remedies for the general aching which characterize the **onset** of so many febrile affections. He has often aborted an **acute tonsillitis** by giving early a dose of the tincture of aconite sufficient to cause this drug's specific sense of constriction of the throat. He believes its action is further promoted by the addition of a small dose of Dover's powder. He combines **phenacetin** with **quinin**, and believes that these two drugs may possibly act as antitoxins to the influenza poison. He recommends a prescription containing in each dose, $\frac{1}{4}$ grain of solid extract of aconite, 1 grain of Dover's powder, 4 grains of phenacetin, and 3 grains of quinin, made into 2 pills. Six pills are to be taken on the first day of the attack, and continued as long as the fever lasts. When **coryza** and **nasal catarrh** are leading symptoms he advises a pill of $\frac{1}{4}$ grain of belladonna, with a grain or two of camphor. To this may be added, flushing of the throat with a fountain syringe, with a solution containing a quart of hot water, to which 2 teaspoonfuls of potassium chlorate and 5 drops of oil of peppermint are added. In those cases in which the supraorbital sinuses become involved with generally periodic attacks of pain, and often photophobia, he has found an extract of ergot in dram doses, repeated every 3 hours, if necessary, to be a specific. In the dry cough which so frequently follows influenza, he has long recommended an emulsion of linseed oil. Adjuvants to this general treatment are advised when indicated, and especial importance laid upon complete rest in bed. [T.L.C.]

Medical Record,

January 26, 1901. [Vol. 59, No. 4.]

1. Early Diagnosis of Mammary Tumors. GEORGE F. SHRADY.
2. Some Further Work on the Mosquito-Malaria Theory, with Special Reference to the Conditions Around New York. WM. N. BERKELEY.
3. The Causation, Prevention, and Cure of Gout. ALEXANDER HAIG.
4. The Nonmyxomatous Character of Nasal Polypi. JONATHAN WRIGHT.

1.—Shrady, in making a plea for early diagnosis in all **growths of the mammary gland** discusses in detail the differential diagnosis between carcinoma and the other tumors of the breast. Among the early symptoms of cancer is the "dimpling" of the skin over the growth, and this the author thinks of the greatest significance, coming on before retraction of the nipple oftentimes. This sign is seen in even deep-seated cancers. The "tumor test" of stroking the breast with the flat of the hand while the patient is recumbent, will always reveal the presence of the growth. These two signs, with darting pains, are, in Shrady's experience, the earliest signs of cancer. With such symptoms the patient should see a surgeon at once. He emphasizes the fact that no mammary tumor can be trusted and that the chances of malignancy are very great. To make a diagnosis of a "simple tumor" one must be very sure of his ground. The diagnosis has a most important practical bearing on ultimate results. Probably 90% of breast-tumors in older women are malignant. Even adenomata are best removed, as malignant changes in them are not an impossibility. [J.H.G.]

2.—William H. Berkeley presents some further work on the **mosquito-malaria** theory, with special reference to conditions around New York. He touches upon: 1. The local species of Anopheles and their natural history. 2. Inoculation experiments. 3. The incubation period of malaria. 4. Prophylaxis and eradication of the malaria endemic in our own locality. Of the three species of Anopheles, native of North America, he has found two around New York: *A. quadrimaculatus* Wiedemann and *A. punctipennis* Say. He describes structural differences between Culex and Anopheles. Anopheles was never found without Culex. Oftenest *C. pungens*. Anopheles was found always in buildings, oftenest on walls and ceilings of recently used bed-rooms, and was far more abundant in the dwellings of the poor. The adults were not found out of doors. Berkeley has placed early March as the period in the spring when the female begins to bite. He found Anopheles as late in the fall as November 6. He determined experimentally that the time from egg to adult does not occupy more than 19 days, and believes that care of the larvae would have further shortened the period. He performed a series of inoculation experiments and succeeded after repeated trials in inoculating *A. quadrimaculatus* with tertian parasite. He was unable to bring about infection in man from the bite of a single infected mosquito. As to the period of incubation between the bite and chill, he reports one case with a clear history in which it was exactly 14 days. As to the prophylaxis he believes the Health Department should require malarial cases to be reported, and that every house should be thoroughly inspected and the inmates instructed to kill all the Anopheles in the house; to provide the windows and doors with screens; to use every precaution to isolate the patient from mosquitoes, and to cause all the standing water in the vicinity to be drained, or heavily petroleized. Rigid treatment with quinin should be insisted upon. [T.L.C.]

3.—Haig gives a general review of his now well known theory concerning the **etiology of gout and rheumatism**. He does not accept the bacterial origin of rheumatic fever, and believes in the identity of gout and rheumatism. His theory makes uric acid in solution responsible for the attacks in both diseases. He does not believe that the salicylates are at all times a useful remedy in rheumatic condition, but that frequently they may do harm rather than good. His chief points in treatment are, that uric acid being a poison should be introduced into the body in as small quantities as possible, and to this end dietetic measures are important. Again it is urgent to provide for the elimination of poison already in the body. It is especially important to

see that a proper quantity of albumin is taken in proportion to the body-weight. In some acute and chronic conditions we should aim to diminish the alkalinity of the blood which is high, for the purpose of favoring the best action of the salicylates. The same principle holds for the acute arthritis of gout. Give the salicylates alone and plenty of them, and on no account with alkali or colchicum, as these increase the alkalinity of the blood. During this treatment he does not cut off wine or cut down meat, for both tend to keep up the acidity of the urine and diminish the alkalinity of the blood. He believes that the high blood-pressure of chronic gout is due to large excess of uric acid in the blood and recommends the iodid of sodium more or less aided by the chlorid and bromid of ammonium and chlorid of sodium. [T.L.C.]

4.—Jonathan Wright calls attention to the histologic error of classing **nasal polypi** as myxomata. As the result of a careful study of polypi, he has found some mucin and occasional embryonal new connective-tissue cells. There is little or no new formation of tissue, but, on the contrary, a separation of the fibers of the preexisting subepithelial stroma serves effusion. [T.L.C.]

Medical News.

January 26, 1901. [Vol. lxxviii, No. 4.]

1. Lakewood as a Winter Resort. WM. GRAY SCHAUFFLER.
2. The Climatic Treatment of Chronic Bright's Disease. JAMES TYSON.
3. Treatment of Syphilis at Hot Springs, Ark. JAMES T. JELKS.
4. Some Topographical and Climatic Features of the Florida Peninsula; with Special Reference to its Adaptiveness as a Winter Health Resort. JAMES K. CROOK.
5. The Climatology of Neurasthenia. F. SAVARY PEARCE.
6. The Tonsils as Portals of Infection. JULIUS ULLMAN.

1.—W. G. Schauffler believes that **Lakewood, N. J.**, possesses valuable physical characteristics as a winter resort and lays stress upon its accessibility and its economic features. The greatest factor in its favor is its **comparative warmth and low humidity**. A point observed has been that in the cold weather when the thermometer fell below the freezing point the day was invariably bright and sunshiny. Damp days are the exception. He recommends the place for convalescents and neurasthenics as well as those suffering from **asthma and bronchial affections**. [T.L.C.]

2.—James Tyson and F. M. Tyson, discuss the general principles of the climatic treatment of chronic Bright's disease. They conclude that there should be as little **cold, moisture and variation** as possible and that **hot dry climates** should be more beneficial than a cold, dry climate; either is better than a temperate climate, such as that found in the United States, with ground saturated with moisture and consequent dampness, with sudden changes of temperature, and marked differences between night and day temperatures. The effect of high winds is highly detrimental. The mortality from renal disease is highest in the Middle Atlantic Coast region, next in the North Atlantic and least in the Southern Central region. In considering these figures we must not fail to take into account the greater centers of population with their accompanying diseases, as syphilis, scarlet fever and pneumonia, which predispose to Bright's disease. Also the habits and surrounding conditions of those of the great cities. In deciding upon a fit climate to send our cases to, we must beware of high altitudes if the patients suffer from a failing heart, or one that has already lost compensation. [T.L.C.]

3.—Jelks considers the very favorable results of the treatment of **syphilis at Hot Springs, Arkansas**, and believes this to be due to the favorable **hygienic surroundings**, and complete absence of business cares and worries on the part of the patients. The eliminating organs are stimulated by **bathing and drinking of the hot water**. It is found that large doses of the acute syphilitic remedies are well borne. As high as 50 to 100 grains of the iodide salts may be safely given at a dose three times a day. The author prefers **mercurial ointment** to any other form of the drug. It is found that this too is well borne in large doses. [T.L.C.]

4.—Crook discusses the climate of Florida and its adap-

tiveness as a winter resort. He believes that the climate benefits (1) those patients who suffer from recurrent bronchitis; (2) those with predisposition to tuberculosis but who present no recognizable lesions of the disease; (3) those cases of beginning phthisis without cavity formation; (4) cases of fibroid phthisis; (5) The large valetudinarian class, composed of old rheumatics, victims of subacute or chronic gout, asthmatics, and intractable cases of chronic rhinitis, pharyngitis, laryngitis, lumbago, neurasthenia, and general debility. [T.L.C.]

5.—F. Savary Pearce considers the **climatology of neurasthenia**. He points out that an altitude of over 2,000 feet is unsuitable as well as districts menaced by high winds, and frequent fogs, cloudy, saturated atmospheres with but slight movements of air-currents, low country (sea-level), with continuous, non-varying, although moderate heat as Bermuda and Florida. The ideal climatic conditions for the neurasthenic include sea-air in a well-wooded country, far enough from the coast to avoid fogs. A sea-voyage, provided it be not stormy, will also prove beneficial. [T.L.C.]

6.—Julius Ullman studies the **tonsils as portals of infection**. In his article, to which is added a copious biography, he concludes: (1) That the normal tonsil has a physiological function, probably protective to the organism; (2) however, this function is frequently impaired and the tonsil becomes the nidus for the growth and distribution of pathogenic organisms in the system; (3 and 4) that in many grave processes as scarlatina, the tonsil is the point of infection; (5) the relation between endocarditis, chorea, rheumatism and the diseased tonsils found in cases of these conditions; (6) in rare cases of typhoid fever in which no intestinal ulceration can be demonstrated, the similarity of the tonsillar tissue to Peyer's patches suggests the possibility of bacterial infection through the tonsil; (7) that scrofulosis is often associated with diseased tonsillar tissue, and this is often the point of selection of the tubercle bacillus; (8) he concludes that much could be accomplished by careful post-mortem studies of the tonsils, which are too seldom examined. [T.L.C.]

Boston Medical and Surgical Journal.

January 24, 1901. [Vol. cxliv, No. 4]

1. A Short Abstract of the Early History of Medicine in Massachusetts to the Year 1800. ELBRIDGE G. CUTLER.
2. The Great Toe (Babinski) Phenomenon: A Contribution to the Study of the Normal Plantar Reflex Based on the Observation of 156 Healthy Individuals. MORTON PRINCE.
3. A Case of Obliteration of the Right Ureter by a Calcified Fibroid; Removal of Fibroid and Implantation of the Ureter into the Bladder; Recovery. MAURICE H. RICHARDSON.
4. A Case of Vesical Implantation of the Ureter by Dudley's Forceps Method after the Failure of Several Plastics. EDWARD REYNOLDS.
5. Pregnancy Following Removal of Both Ovaries and Tubes. M. A. MORRIS.

2.—In order to acquaint himself with the exact character of the **normal plantar reflex**, Prince has lately examined the reflex in 156 presumably healthy men between the ages of 22 and 33 years, all candidates for civil service examination. As a result of these observations the author has been able to satisfy himself that one cause of the discrepancies in the reported observations of different authors is that there may be 2 distinct plantar reflexes, one of which is probably cerebral and one spinal. Both may be absent. The normal spinal reflex movement of the toes in the adult is always, as shown by Babinski, flexion; the normal cerebral reflex is generally extension of the toes and of the foot. If precautions are not taken the cerebral reflex may mask the spinal reflex and give erroneous results, that is, override the spinal flexion and produce an extension. The cerebral reflex can generally be inhibited by an act of will and thus leave the spinal reflex free. With proper precautions taken to inhibit the cerebral reflex, extension of the great toe was not observed once in 92 individuals. In 64 individuals it was only observed once; but in this case the extension of the great toe was slight and was in all probability a cerebral reflex, since

insufficient precautions were taken. The significance, then, of the Babinski phenomenon consists in the extension of the great toe. To emphasize this the best term would be the **great toe phenomenon**. The author believes that the frequency of the spinal plantar reflex, so far as it concerns the toes, has been exaggerated owing to several sources of fallacy having been overlooked, such as (1) mistaking the cerebral for the spinal reflex; (2) in stroking the sole it is not difficult, by moderate pressure over the first phalanges, to cause a purely mechanical flexion of the toes; (3) if the stroke is made from the toe toward the heel, pulling on an elastic skin will do the same. [J.M.S.]

3.—Richardson reports a case that illustrates the **danger of neglecting an old fibroid**. The patient was a woman, aged 58 years, who had always been well until 10 years before the author saw her. At that time the patient noticed a tumor in the lower portion of the right side of the abdomen that gradually increased in size. The tumor was painful and was accompanied by frequent and painful micturition and sometimes by incontinence. On examination, the tumor was found to be fluctuating and it was thought to be an ovarian cyst. On exposure, the growth proved to be a **fibroma of the uterus** on the right side of which there was a large cyst and there were several **calcified areas** near the cyst. As the operation progressed the cyst was torn and was found to be a **dilated ureter**. The divided ureter was sutured into the bladder. On removing the left half of the tumor the sigmoid flexure was torn and the opening was closed by silk sutures. The patient made a complete and uneventful recovery. [J.M.S.]

4.—Reynolds reports the case of a woman, aged 45 years, who, following a complete vaginal hysterectomy, suffered from an **ureterovaginal fistula**. After several plastic operations the author **implanted the ureter into the bladder by Dudley's forceps method**. The operation was followed by complete relief. [J.M.S.]

5.—Morris reports the case of a woman who was subjected to **double oophorectomy**. Soon after the operation, which was successful, the patient began to menstruate, which function continued regularly and painlessly for 4 months. Fourteen months after the operation the patient was delivered, after a **normal labor**, of a healthy girl baby. The child died when it was about 3 weeks old, and soon after that the patient again began to menstruate and has continued to do so regularly and normally since. [J.M.S.]

15. Some Remarks on the Plantar Reflex, with Special Reference to the Babinski Phenomenon. J. T. ESKRIDGE.

1.—In an article on diabetes mellitus, Herrick calls attention to the many symptoms or complications accompanying

this condition which are lightly passed over by the physician, the observations of which would lead to an early diagnosis. Among the derangements of the nervous system he calls attention to the neuritic pains in the legs, with loss of the patellar reflex. The trophic changes are falling out of the nails, bullae, herpes zoster, perforating ulcer, etc. Occasionally there are peripheral paralyses, cerebral palsies, monoplegia, and even hemiplegia, without anatomical lesions which can be demonstrated after death. Headaches and dizziness often lead the patient to consult a physician. The eye may give indication of diabetes by paresis of the external rectus muscles. Retinitis and atrophy of the optic nerve, the development of bilateral cataract in early life should lead one to suspect diabetes. Furuncles of the external ear and suppuration of the middle ear with early involvement of the mastoid may occur. The conditions which deserve especial attention are sexual impotence and psychic disturbances, irritability of temper, suicidal tendency, etc. Of the alimentary tract he lays stress upon dilation of the stomach without alteration of its functions. Vomiting and diarrhea, if persistent, may be forerunners of coma. Cirrhotic liver is often present with bronzing of the skin. The examination of the blood is of little value, though the color reaction of Bremer and Williamson might enable one to recognize diabetes without glycosuria. The presence of acetone, Beta oxybutyric acid, and the amount of ammonium excreted are of value from the standpoint of diagnosis and prognosis. The urine in diabetes has a tendency to undergo rapid fermentation, which may occur in the bladder and produce cystitis. After the attention has been called to the urine, the diagnosis is usually readily made, but owing to certain errors may be sometimes overlooked. The sources of error may be (1) in the technic of the examination for sugar; (2) the urine may not be examined by the physician; (3) that there is no sugar present at time of examination. Emphasis is laid on the fact that casts are found in the urine during diabetic coma and that their presence may give warning of the approach of coma. The specific gravity of the urine may be low after the ingestion of large quantities of fluids, although the amount of sugar present is large. Should chronic interstitial nephritis supervene the amount of sugar may decrease or entirely disappear. In conclusion he calls attention to the importance of recognizing the variety of the disease, noting particularly the age, tendency to obesity, heredity and any organic disease as etiological factors. The severity of the disease depends not always upon the amount of sugar present, but rather upon the amount in comparison to the carbohydrates in the diet.

2.—Stein discusses the mortality of diabetes mellitus in the city of New York during the period from 1889 to 1899, inclusive. In this article he gives elaborate statistics, the total number of deaths in this period was 1,867. He also gives a number of tables as to death-rate per thousand population, the mortality during the months of the year, the number of deaths occurring in males and females and their age. [F.J.K.]

3.—The cutaneous lesions which accompany diabetes are discussed by Hartzell. He states that the first noticeable symptoms may be due to inflammatory disease of the skin. In the late stages of the disease dryness and scaling of the skin accompanied by general pruritus, falling out of the nails and thinning of the hair occur. He states that the pruritus is often confined to certain regions of the body and that eczema is not at all uncommon. Erythema and urticaria, especially of the chronic type, are also encountered. Acne, painful furuncles and carbuncles are especially likely to occur in elderly subjects, and that both dry and moist gangrene are serious complications in the course of diabetes. Xanthoma diabeticorum is a very common form of eruption, and bronzing of the skin also takes place in this disease. In the early stages purpura may be a complication. In the management of these skin affections attention must be directed to the underlying cause and the skin lesions treated as those occurring in cases that are not of diabetic origin. [F.J.K.]

4.—In an article on postanesthetic paralyses, Hersman lays particular stress upon that form of paralysis due to pressure upon nerve-trunks. The most common paralysis is that due to pressure upon the brachial plexus. During anesthesia faulty positions of the patient should be guarded against as much as possible by the surgeon, in order to

obviate medicolegal complications. As a rule, recovery rapidly follows these forms of pressure-paralyses unless there be previous degeneration or atrophy of the nerves. As to treatment he recommends the use of strychnia and massage, and electricity for those cases which do not show nerve atrophy. [F.J.K.]

5.—Brower in discussing the treatment of neurasthenia states that a very important indication in the treatment is mental and physical rest. The great majority of cases simply require partial rest, absolute rest being injurious to some of the cases. The second indication is the dietetic management. The food should be of a nitrogenous character and as free as possible from sugar and sugar-producing articles. In some instances predigested foods are very valuable articles of diet. The third indication is the use of electricity, faradism being employed in the absolute-rest cases, while he recommends static electricity in the partial-rest cases. He states that hydrotherapy is the fourth indication and recommends a daily wet pack in those cases which are being treated by absolute rest. In the partial-rest cases the shower bath, using either warm or cold water, the hot-air bath and the wet pack are recommended. Massage should be employed for the absolute-rest cases, while the partial-rest cases may or may not need this measure of treatment. He does not favor long voyages for patients suffering from neurasthenia, but if a change of climate is necessary moderate mountain elevation should be selected. He likewise does not find it desirable for the patients to make a long stay at a sanitarium. As to the medicinal treatment, laxatives should be frequently used. Diuretics are sometimes of service, and for the nervousness he believes the bromids are invaluable. For the anemia Bland's pills are of use. An alternative is sometimes indicated. The one which he prefers is chlorid of gold and sodium. In the dyspeptic cases, the mineral acids are often of use and in the cases which show a malarial element quinin is recommended. He concludes by saying that the patient should be kept busy by following a regular therapeutic schedule. [F.J.K.]

6.—Trumpp refers to the former disinclination of European surgeons to practice **intubation**, excepting in the hospital, where constant watch could be kept over the patient. In making recent inquiry of American and European surgeons he finds few who do not think the operation as useful in private as in hospital practice. The percent of recoveries due to the use of serumtherapy has been more than doubled. He thinks the parents should be left to decide between intubation and tracheotomy, both methods being explained to them, and that no inexperienced physician should attempt the operation. The patient should always be under the surveillance of a reliable person. He strongly urges the use of the O'Dwyer hard-rubber tubes in preference to those of silver. They are much lighter, and therefore less liable to produce ulceration; they adhere more readily to the mucous membrane, and hence are not so easily expelled during fits of coughing. His experience goes to prove the point. He proposes some slight change in the tube and obturator which will render introduction easier, and a slight curve backward in the tube to prevent pressure. [J.H.G.]

7.—Von Bokay, under **traumatism during intubation**, first discusses the injury to the mucous membrane and the formation of a false passage, in introducing the tube. In 1,200 cases seen by him, a false passage was made in 4 cases, which he reports in detail. The diagnosis of the condition is made by the fact that respiration is not impaired by the presence of the tube, but becoming obstructed entirely in a short time; the tube may be felt to occupy an oblique position; the tube may be felt under the skin in front or at the sides of the larynx; on its withdrawal there may be a flow of blood. Emphysema may also occur. Later, inflammation develops around the larynx and an abscess may form. No cure can take place after the formation of a false passage, except a tracheotomy is done. The injury is usually done by careless handling of the instrument, but may be due to a faulty tube. He thinks the sitting position the best in which to introduce the tube. Introduction should be accomplished by keeping the instrument in the median line, or injury to the mucous membrane is likely to occur. After the formation of a false passage the tube should immediately be withdrawn and tracheotomy performed. [J.H.G.]

8.—Barton speaks first of the very unsatisfactory results

obtained in the nonoperative treatment of **fracture of the patella**, mentioning the long confinement to bed, the prolonged fixation of the joint and the so frequent ankylosis. The mortality of the operative methods is very small. Powers reports 711 cases with but 3 deaths, due to sepsis, and Phelps reports 420 operations by New York surgeons with no deaths from sepsis, 1 from delirium tremens, and 1 from carbolic-acid poisoning. Barton thinks that no case should be denied operation because facilities are not at hand within a day or two of the accident, for a little delay is not injurious but of advantage and the patient can always travel without great discomfort. He thinks that in all cases of fracture from muscular contraction there will be found tissue between the fragments which will make bony union an impossibility. The suture should pass through the fragments and not about them, or in the tissues covering them. The suture is brought out on the fractured surface and does not pass all the way through the bone because this irritation of synovial membrane renders manipulation difficult. He uses a suture of heavy silver wire. The best time to operate is about 10 days after the accident unless the fracture is compound, when it should be done at once. Drainage is not usually required. A rigid asepsis is insisted upon. In closing the wound he does not carry the superficial sutures through the entire thickness of the flap lest they be the means of infecting the joint from contact with the skin staphylococcus. [J.H.G.]

9.—Hamilton urges the high mortality of **growths of the frontal sinus** as a reason for early diagnosis and early operation. He reports two cases. 1. A man, aged 36. Growth followed an injury received at age of 14 years. At operation the frontal bone was found thinned and the meninges were exposed. An osteoma, very dense, was removed in fragments, which weighed 4½ ounces. The patient recovered and is attending to his work. 2. A man, aged 27 years. Growth first noticed 3 years before. Besides a prominence over the root of the nose, he had double exophthalmos, interference with vision, and double optic neuritis. The growth in this case was much softer than in the first, and a number of polypi were also found in the sinuses, with an accumulation of mucus and pus. Destruction of the orbital roofs and exposure of the dura were present. The patient recovered with a sinus, but all trouble with the vision disappeared. This growth also proved to be an osteoma. [J.H.G.]

10.—The treatment of **gastrointestinal symptoms in typhoid fever** is discussed by Anders. He states that the medicinal treatment in this condition is subsidiary in importance to such measures as bathing, feeding, nursing, and the proper use of stimulants. In typhoid patients, nourishment should only be taken in a liquid form. Milk, if well borne, should be the chief article of diet. He believes that by regulating the amount and character of the nourishment many symptoms relative to the gastrointestinal tract may be entirely prevented or diminished, thereby rendering medicinal agents unnecessary. He states that the treatment as recommended by Brand has a favorable influence upon the gastrointestinal tract. He advocates the administration of hydrochloric acid after each ingestion of food for deficient gastric secretion, and adds that intestinal antiseptics are valueless in checking the growth of the *Bacillus typhosus*. In the early stages of the disease he employs calomel, and if constipation exists during the entire course, this should be treated by enemata of soapsuds. During convalescence, diarrhea is often checked by a mild laxative. He protests against any specific treatment. Anders uses salol, which he believes has an inhibitory action upon fermentative changes. He recommends turpentine for distention of the bowel, and enemata of oil of turpentine with asafetida when the stomach becomes intolerant. He advocates the use of intestinal irrigation, if judiciously employed, in properly selected cases. Injection of cold water into the rectum may be of service in some cases. [F.J.K.]

11.—Reilly in an article entitled **The unbroken skin as an absorbing medium**, states that the dose of a drug when applied to the skin may be quadrupled in most cases, and that the essential features in absorption are that the drug should be volatile during its application, or that the medicinal agent should be combined with a fatty base. In the latter instance friction should be employed when it is applied. He states that the crypts of the sebaceous glands

are the structures through which absorption occurs. Finally, he adds that the unpleasant effects of some drugs are sometimes prevented when the administration is through the skin. [F.J.K.]

12.—Bernheim discusses **idiosyncrasy as to mercury** and reports a case of **erythema mercuriale** in a woman 50 years of age. The eruption resembled that of scarlet fever and was followed by furunculosis. She had a number of attacks of this eruption during her life which always followed the administration of mercury. [F.J.K.]

13.—Andrews offers a new method of diagnosing mastoid disease. A small stethoscope is placed over the tips of the mastoid, and the handle of a vibrating tuning fork over the antrum. If the cells are obliterated or filled with pus or granulations the sounds are much more perceptible than on the opposite or healthy side. [J.H.G.]

14.—The author calls attention to the fact that **ocular manifestations** occur with sufficient frequency in **systemic affections** to be of great value in diagnosis. While the conditions of the eye-ground in the advanced stages of general diseases have received careful attention and study, the earlier conditions on the other hand also require careful scrutiny and investigation. Ocular complications, while they may exist in all forms of diabetes, are generally found in chronic cases. The patients generally present themselves for supposed errors of refraction. The author quotes a few cases on record in which hypermetropia was caused by diabetes and which fluctuated in amount with variations of the quantities of sugar in the urine. According to Landolt, this is due to a change in the index of refraction of the vitreous. Paralysis of the external ocular muscles are supposed to be due to a peripheral neuritis or to even nuclear or peripheral hemorrhages. Paralysis or paresis of accommodation is a frequent early symptom. The author believes that cataract occurring in diabetes passed middle life is due to a general disturbance of nutrition and arterial degeneration; in the young on the other hand, there is some direct relation between the eye and the general disturbance. He coincides with Hirschberg, that there is a distinct diabetic retinitis, characterized either by a degenerative or hemorrhagic type. Retinal hemorrhages with or without other changes in the retina, accompanied or unaccompanied with conjunctival hemorrhages are always suggestive of diabetes. Symptoms of toxic amblyopia frequently occur in diabetics, without a history of excessive indulgence in either tobacco or alcohol. Plastic iritis is encountered in diabetes. Keratitis, which is notably an exponent of nutritive disturbances occurs in this disease. Atrophy of the optic nerve and amblyopia without any assignable cause are occasionally met with in diabetes. [M.R.D.]

15.—Eschridge in an article entitled **Some remarks on the plantar reflex with especial reference to the Babinski phenomenon** comes to the following conclusions: That from the standpoint of diagnosis and probably in prognosis the Babinski phenomenon is valuable, but that in regard to organic disease of the lateral tract it cannot be considered a pathognomonic sign. Further he adds that a pseudo-Babinski phenomenon may be due to several poisons, and finally he makes a plea for more extensive and careful investigations. [F.J.K.]

3. Brief Communications on the Therapeutics of Skin Diseases. SEIBERT.
4. The Treatment of Biliary Calculi with Olive Oil. WITTHAUER.
5. The Treatment of Intestinal Obstruction with Atropin. MARCINOWSKI.
6. A Case of Thoracopagus. TOFF.
7. Bertillon's Method for the Measurement of the Body, Presented in a Practical Form for Physicians. WENGLER.
8. Contribution to the Knowledge of Lithopedons. KROEMER.

1.—Roos has performed some interesting experiments in reference to a novel idea in regard to constipation. In the first place it occurred to him that perhaps the colon bacilli

of a constipated person are more or less responsible for the condition, and therefore he fed these people with cultures of this microorganism obtained from the intestines of persons with normal bowel movements. Seven persons submitted themselves to this experiment, 5 of them suffering from chronic constipation. Three of these experienced a moderate laxative effect lasting for about 14 days. No particular effects were observed in the others. In 2 persons suffering from chronic constipation, the same treatment was employed, and 1 of these was greatly relieved. Dead colon bacilli, killed by fractional sterilization, were also employed, but the results were very slight. The *Bacillus aerogenus lactis* was also tested, but it was inactive, and lactic acid likewise proved useless. Roos then, after a careful consideration of the literature of the subject, discusses his results of the administration of the ordinary brewer's yeast. This was employed in 20 cases; in 4 without result. In 2 cases it produced liquid stools, and in the remaining merely a slight laxative effect. Sometimes, however, it was necessary to repeat the treatment for several days before any result was obtained. In several cases the results were brilliant. One in particular, a girl of 24 years, was relieved for the entire period of subsequent observation, even after the treatment has been discontinued. Further experiments upon 18 persons with yeast that had been destroyed by exposure to 100° for 10 hours, showed that it was quite as effective as the living preparation, positive effect occurring in 14 of the cases, and Roos believes that the plant probably contains a substance that exercises a moderate irritation upon the intestinal canal. [J.S.]

3.—Seibert has employed epikarin in tabs with very excellent results. The drug resembles naphthol, and is produced by the introduction into the naphthol molecule of a carboxyl group, by the means of a cresotic acid. A 10% salve is rubbed all over the body, but particularly in the parts chiefly involved, for 3 successive days. On the fourth day the patient is bathed, and any lesions still remaining treated by the ordinary method. There was only one failure in all the cases treated. The remedy does not relieve the itching and does not improve the eczema that is often also present. It is, however, very convenient and not in the least injurious. In the vulvovaginitis of small children he has employed protargol in 0.5% to 1% solutions. This is used as an injection 3 times a day until the symptoms of inflammation have been relieved. In nearly all the cases, gonococci were present. He has also employed ichthalbin in cases of furunculosis, in which it apparently is of no particular benefit, and in urticaria, in which there certainly seems to be some favorable influence. The remedy was given in doses of 5 gr. 3 times a day to children.

4.—Witthauer has employed olive oil in cases of biliary colic with brilliant success. He gives it first by the mouth in 1-ounce doses, to which a few drops of oil of peppermint have been added. When in the course of time the patients find themselves unable to continue, he employs it in the form of an enema, about 400 to 500 cc. being injected at first every day, and later at longer intervals. He reports 3 cases in which large numbers of stones were successfully and permanently removed by this method, without resort to operation. [J.S.]

5.—Marcinowski reports 2 cases of intestinal obstruction. The first, a woman of 32, after lifting a heavy weight, was attacked by severe pain in the abdomen and went into collapse and vomiting. Opium failed to relieve the symptoms, and $\frac{1}{5}$ of a grain of atropin (0.05) was injected hypodermically. The patient improved very rapidly, an exudate that had formed, disappeared, the bowel-movements became normal and ultimately the patient recovered. In the second case, a man with double hernia suffered from incarceration as a result of a fall. There was severe pain, active peristaltic movements, and bowel constriction. An injection of a similar dose of atropin relieved the symptoms. [J.S.]

7.—Wengler gives a brief but sympathetic description of Bertillon's method for the identification of criminals, and calls attention to its great value to science on account of its extraordinary accuracy. [J.S.]

October 30, 1900. [47. Jahrg., No. 44.]

1. Albumen and its Artificial Oxidation. F. N. SHULTZ.
2. Estimation of the Freezing Point of Blood and of Urine in

Determining the Functional Ability of the Kidneys before Operation. HERMANN KÜMMELL.

3. The Process of Compensation. ADOLPH BICKEL.
4. Mixed Infection with the Influenza Bacillus and the Bacterium Proteus. HANS DOERING.
5. The Substitution of Eucaïn B for Cocain in Cocainization of the Spinal Cord. FRITZ ENGELMANN.
6. Some Little-Known Pupil-reactions and their Therapeutic Significance. HANS KIRSCHNER.

1.—After a review of the chemists' investigations which ended with the crystallization of albumen, Schultz explains the composition of the albumen molecule and its reactions. He ends his very technical article without solving the old problem, why albumen outside the body so energetically resists oxidation, while the albumen of the human organism is so easily oxidized during life. [M.O.]

2.—To find the functional ability of the kidneys before operating, Kümmell—besides advising routine urine analysis, and its examination after subcutaneous injections of different substances (methylene-blue, or phloridzin) with catheterization of the ureters; when normal, the urine from both kidneys would be alike; when one is affected, the urine secreted by the diseased kidney would contain less of the foreign substance than the other—recommends strongly the determination of the freezing point of the blood, which he gives as 56° C. below that of distilled water, normally; if below 58° C., there is renal insufficiency, and the determination of the freezing point of the urine from each kidney, collected by catheterizing the ureters, which, in normal cases, is almost equal, but shows a great disparity when one kidney is affected; the urine from the diseased kidney freezing at a much lower temperature than that taken from its fellow. He uses Beckmann's method of freezing. Three cases are given, in which his diagnosis thus established was confirmed by operation. [M.O.]

3.—Ewald has divided the process of compensation in anatomic defects of the nervous system into (temporary) reparatory phenomena, and (permanent) degenerative phenomena. Bickel gives a series of experiments performed upon lower animals from frogs up to dogs; from which he concludes that the more highly developed the nervous system, the easier and the more widespread become these reparatory processes. He mentions the clinical usefulness of these experiments in many diseases of the nervous system, especially in *tabes dorsalis*. [M.O.]

4.—During the last year Doering saw 152 patients with influenza, 41 of whom had complications. Pneumonia was the most frequent complication. True mixed infection was seen in 13 cases; in 8 with staphylococci, and in 5 with streptococci. In two cases the bacterium proteus was found besides the influenza bacillus. The great destruction found throughout the body, and the bacteriologic investigations are fully described. [M.O.]

5.—Engelmann tested Eucaïn B, which is said to be less poisonous and yet as effective as cocain in producing general anesthesia, when injected into the spinal canal. With one injection of 0.01 ccm. of Eucaïn B, the only effect was a slight paresthesia, no anesthesia at all. His sensations are concisely described. [M.O.]

1. A Collective Statement of the Results of the Malaria Expedition. R. KOCH.
2. Concerning Athyreosis in Childhood. QUINCKE.
3. A Preliminary Communication Concerning the Injuries in the Heidelberg Railroad Catastrophe of October 7 1900. F. VOLCKER.
4. On the Technic of the Elicitation of the Patellar Reflex. WALBAUM.

1.—Koch continues his article. He thinks that the frequently observed decrease in the intensity of the attacks and the appearance of irregular fever are further proof of the occurrence of acquired immunity. He believes, however when splenic enlargement, anemia, and other such symptoms exist, the patient should be considered still a subject of malaria and should be so treated. In such cases para-

sites can frequently be still discovered. In the management of malaria he again lays strong emphasis upon his recommendation of the use of quinin for prophylactic purposes. He thinks that all those who are strongly suspected of malaria or who are proved to have it should be given quinin in order to prevent the development of the parasites. He insists upon the difference between this recommendation and the mere taking of quinin to ward off malaria. In the latter case one merely prevents infection; in the first case one is fighting the parasites which are already lodged in the patient. So far as has been discovered man and mosquito are the only hosts of the parasite. Koch gives a series of tables to show the decrease in malaria in certain regions in Germany since quinin has been freely used. General hygienic measures can produce some good results, but they cannot prevent the disease. In carrying out the quinin prophylaxis it is very important to have a considerable body of skilled assistants searching for parasites. If this cannot be done regular records of the temperature should be kept. Methylene-blue, he finds, next to quinin, to be the most valuable drug, but it works much more slowly than quinin. It is useful when there is a tendency to blackwater fever. He advises the use of only good preparations of quinin, preferring the hydrochlorate, strongly opposing the use of pills; oblates he considers the best method of administering quinin in children and often under other circumstances a solution is best. It is usually best taken in the morning on an empty stomach, when it is quickly and rapidly absorbed. It is often well to give hydrochloric acid with it, or if the stomach is not in good condition to give it hypodermically. It should not be given in doses of less than one gram for adults. It should be administered from 4 to 6 hours before the attack; it is repeated the next morning, and if the attack has not been prevented the dose is increased. On the following morning another dose is given. Using these measures over 500 severe cases have been treated and none lost. To prevent return of the malaria attacks Koch used various methods of administering quinin. He finally decided to give quinin on two consecutive days, repeating this at an interval of 10 or 11 days. If the cases are particularly persistent the time between the doses is reduced to 7 or 8 days, or the dose is increased, the latter perhaps being the better procedure. This treatment should be carried out for at least 2 months, even though the patient lives in a malarial region. It is important to look out for the possibility of blackwater fever in persons who have had malaria before. One should begin with only a grain and a half or two grains of quinin, increasing it very gradually and watching the urine. If a rise of temperature occurs after taking quinin, if the urine appears darker, or if there is a tinge of icterus, the quinin dose should not be increased or should be decreased at once, as these signs are the early indications of blackwater fever. As to other diseases he saw but 3 cases of typhoid, which were all imported; tuberculosis was uncommon; beriberi was quite frequently seen, but was always imported, and evidences of its infectious character were readily seen. This disease quickly gave way to treatment by rest and careful nursing without medication. Syphilis occurred, but was not common. Skin affections were extremely common. [D.L.E.]

2.—Quinke reports another case of **athyreosis** which occurred in a child. It had been a healthy infant and had begun to speak. When 15 months old the features seemed to change, the psychic growth stopped, and from the nineteenth month on there was loss of intelligence and of the power of speech, the child did not walk, and there were nutritive disturbances, particularly of the teeth. Iodothyryn was used. There was improvement after a week, the child seemed normal after 7 weeks, and remained so after 4 years. The thyroid gland could not be felt in this case. These cases are not instances of ordinary cretinism, though they may have points of resemblance in their clinical appearance and in their response to thyroid medication. They are also not ordinary myxedema, the onset is too acute for the latter disease, while it is not congenital cretinism because the onset and symptoms occurred some time after birth, were progressive, and in one case at any rate was accompanied by progressive decrease in the size of the thyroid gland. The skin too, while it showed changes, was soft and moist, with no definite changes in its volume and consistency, and there were no changes in the sweat secretions or growth

of hair. Quinke prefers to call the condition **subacute athyreosis**. In the second case the remarkable and permanent improvement of the child was very striking. This might be explained by the possibility of the presence of an accessory thyroid which had assumed vicarious and increased function, or by vicarious functioning of the thymus. A striking fact in both cases was the destruction of the teeth. The fact that it was so marked was probably due to the early age of the patients and the acuity of the processes. Quinke thinks that these cases are explained only by the acceptance of some relation to the thyroid gland and the presence of an auto-intoxication. It is probable, he thinks, that other organs than the thyroid are involved in some way. This would explain the very varied reaction to thyroid preparations and the variation in the different symptoms. He thinks also that the thyroid gland probably produces other important substances beside iodothyryn. He considers it extremely important that one should look much more frequently for thyroid changes in children, in order to explain obscure conditions, particularly mental changes, when distinctive cretinoid symptoms are not present. [D.L.E.]

4.—Walbaum recommends the following procedure. The half-closed hand is placed with moderate pressure upon the knee to be examined, the finger tips resting over the inferior patellar ligament, while the thenar and hypothenar eminences lie above and to the sides of the patella, and the patella is thereby grasped between the finger tips and the hollow of the hand. One then strikes this hand a light blow with the closed fist of the other hand. If there is even a very slight patellar reflex one can readily recognize it with the finger tips over the ligament, even when it is not visible. [D.L.E.]

3. Experimental Contributions to the Question of Iron Therapy. F. MÜLLER.

1.—The paper is chiefly a study of the albumin preparation called **roborat**. It was found to be well absorbed, and the assimilation was fairly satisfactory. It was used on 50 patients with satisfactory results. [D.L.E.]

2.—Neufeld's paper is largely a review of the literature of the question of **typhoid bacilluria**, containing nothing especially new excepting the report of 4 cases. He found urotropin valuable in the treatment of the condition, but insists that this drug should be used for a number of weeks, since if this is stopped there may be renewed infection. He directs especial attention to the importance of a typhoid bacilluria in relation to public health, the urine being even more important than the feces because of the prolonged time throughout which it may show infection. The urine of a typhoid case should be examined by the naked eye at least once daily, and if it is cloudy urotropin should be given and continued for several weeks. Other forms of bacilluria may occur in typhoid fever. An instance of the excretion of large numbers of active colon bacilli through the urine is mentioned. He believes that if urotropin does not overcome the bacilluria it may be considered to be not a typhoid bacilluria. He believes that the use of urotropin in typhoid fever in the army would be of the greatest importance. [D.L.E.]

3.—Müller took newborn pups, giving them only the mother's milk and iron-free food for a long time afterward, and in order to increase the anemia frequently abstracted blood. When the amount of hemoglobin had become very low and constant he gave inorganic preparations of iron, and saw a marked increase in the hemoglobin and red blood-cells, while the same increase did not occur in the other animals that were not given inorganic iron. He estimated the total amount of hemoglobin by drawing all the blood possible and washing the animal's circulation with physiological salt solution until the fluid came out completely colorless. He notes that an average of about 10% of the total hemoglobin was retained in the bone marrow. As to the methods of action of inorganic iron he refers to the view that it is due to excitation of the blood-

producing organs to more active function. He thinks that this is the true explanation, and as testimony for this notes that he found a marked increase of the nucleated red blood-corpuscles of the marrow, and there was a marked increase in the mitoses in the marrow. He directs attention to the fact that many preparations of iron have a caustic effect upon the gastric mucous membrane, and in direct proportion to this effect are they badly absorbed. The oxytartrate of iron does not have this influence, nor do Blaud's pills. They should, therefore, be preferred to caustic preparations, such as the tincture of the chlorid. There is no necessity for using complicated organic preparations. Absorption, he states, takes place through the bloodvessels and not through the lymphatics. [D.L.E.]

1. A Reflex-Twitching of the Abdominal Muscle, Observed in Pleurisy and Fibrinous Perihepatitis ("Respiratory Reflex of the Abdominal Wall"). RUDOLF SCHMIDT.
2. The Technic of Enterorrhaphy. HERMANN HINTERSTOISSER.
3. The Subcutaneous Rupture of Tendons. L. KIRCHMAYR.

1.—Schmidt details a case in which a **peculiar reflex-twitching** existed in the upper portion of the right abdominal rectus, without any relation to respiration. This "lightning-like" contraction, reaching up to the fifth right intercostal space, occurs upon deep breathing, toward the end of respiration. It could also be caused by pressure upon the painful intercostal spaces. When the epigastrium is drawn in, in forced thoracic breathing, the reflex is increased. It occurs in persons whose reflexes are excited easily and whose muscles are well developed. [M.O.]

2.—Hinterstoisser reports 4 cases in which he performed **enterorrhaphy**, ligating off the longer end of the resected bowel, and attaching it to the abdominal wall, suturing the shorter end into it, above the point of ligation. He also gives the literature on the subject. [M.O.]

3.—Kirchmayr reports 2 cases in which the terminal phalanx of the index finger was forcibly flexed, with **rupture of the extensor tendon**. He gives a similar case occurring in the great toe, followed by operation, the torn tendons being sutured together, good functional recovery following. He reviews the meager literature upon the subject, and concludes that force applied suddenly or gradually will rupture healthy tendons, while degenerated tendons are ruptured even more easily. [M.O.]

1. The Pathology and Etiology of Fulminating Gangrene. FRITZ HITSCHMANN and OTTO T. LINDENTHAL.
2. The Closure of Defects of the Skull by Bone Implantation. KONRAD BÜDINGER.
3. Illustrative Cases of Intestinal Lipoma. FERD. GROSS.

1.—A man, in good general health, came to the hospital for the relief of ankylosis at the elbow joint, between the ulna and radius. Resection of the radius was performed, and to prevent bony union, a celluloid plate was introduced between the resected end and the ulna. This plate had been sterilized by boiling for 10 minutes before its insertion. A few hours after the operation, the patient began to feel severe pain in the arm. His fingers became almost bloodless and cold. On removal of the bandage the circulation improved slightly and also the sensibility. The condition became worse, however, on the next day, and entire hand was anesthetic, cold, and pale. The forearm had a bluish discoloration, and on opening the wound, a foamy serous fluid escaped. Anesthesia continued, and on the next day the process of **spreading gangrene** was well advanced. Amputation was refused, and with the hope of relieving the condition to some degree, extensive incisions were made. This prevented a further spread of the condition, and eventually the line of demarcation formed, and amputation of the forearm at its lower third was undertaken, 8 days after the first operation. The patient made a good recovery from this operation. A very careful bacteriologic and histologic study was made in this case. In the histologic study no

inflammatory change could be found, and Hirschmann and Lindenthal believe that from this study it may be assumed that in this form of gangrene we are not dealing with an inflammatory process, but with a primary necrosis from gas formation and pressure. This single observation they believe is sufficient to show that the commonly accepted ideas as to the pathology of this condition are incorrect. [M.B.T.]

2.—Büdingen reports a case of a boy 5 years old who was suffering from tuberculosis of the left parietal bone. The diseased area was thoroughly removed with a curet and rongeur forceps, leaving two large defects. Ten days after this operation small plates of bone were inserted in the defects in the skull, these plates having been taken from the os calcis of a freshly-amputated leg. The implanted bony plates healed in their position firmly, and a year after their implantation no trace of a bony defect could be felt. After 4 years the child died of general tuberculosis. On examination of the bone which had been inserted very little change in the region could be found. Büdingen recommends the insertion of such plates of bone to supply defects made in **operations upon the skull**. He considers the os calcis particularly well suited for such implantation and emphasizes the necessity for the strictest antiseptic precautions. [M.B.T.]

3.—Gross states that during the last 40 years, 22 cases of **lipoma of the intestine** have been reported. These tumors are of several forms. They may occupy the lumen of the intestine or its outer wall and they may be sessile or polypoid, single or multiple. He reports the case of a man 47 years old who had cramplike pains in the lower portion of the abdomen coming on periodically and lasting but a few moments. A tumor was made out, about 3 cm. in breadth and from 10 to 12 cm. in length, which disappeared on firm pressure with relief of the pain. The abdomen was not distended, it was everywhere soft, not tender on pressure, nor was there any muscle-spasm. On account of the severity of the symptoms, however, an operation was undertaken, and on opening the abdomen a tumor was found within the lumen of the left part of the transverse colon. The intestine was opened by a longitudinal incision and a mass was found the size of a hen's egg covered with normal mucous membrane. It was attached by a pedicle near the mesentery. This pedicle was divided, bleeding points were ligated, the mucous membrane was sutured, and the intestine closed. A good recovery followed. It is believed that the colicky attacks were produced by partial invagination of the intestine from the dragging of the tumor. [M.B.T.]

Berliner klinische Wochenschrift.

November 19, 1900. [37. Jahrg. No. 47.]

1. The Medicolegal Treatment of Border-line Diseases, Together With Some Remarks on Diminished Responsibility. A. CRAMER.
2. The Effect of Bloodletting on Nitrogen Metabolism. G. ASCOLI and A. DRAGHI.
3. The Morphology of Staphylococcus Albus. E. SAUL.
4. Mothers' Milk. M. COHN.
5. Symptomatology of Facial Paralysis. M. BERNHARDT.

2.—The article deals with the relation of **normal nitrogen metabolism** to the blood. Jürgensen states that bloodletting increases the decomposition of albumin just as febrile processes do. Therefore venesection in fevers is an additional causative factor for albuminuria. This should always be considered when venesection is contemplated in fevers where there is already an albuminuria. The author appends 5 tables showing the effect of bloodletting on nitrogen metabolism. On the days when venesection was performed a decrease in the nitrogen metabolism was observed which, according to the author, is probably due to a beginning regenerating functional activity of the organism. [M.R.D.]

3.—Saul, in experimenting with the Staphylococcus albus, comes to the following conclusions: The morphology of the colonies depends upon the principle of **dichotomy**, not in the botanical, but in the anatomical sense of the term. In determining this it is the number of the centers from which the dichotomous divisions originate that must be considered. The colony is not an unsystematic aggregation of cells, but represents the entity of the highest regularity of which the organism is capable. [M.R.D.]

5.—The author concludes his article by presenting a number of cases which showed that there are cases of peripheral lesions in which there is **no reaction of degeneration**. He states that there are cases where contractions are produced on the affected side, in the muscles near the median line of the chin and lower lip, due to the transmigration of fibers from the unaffected side; these are probably congenital. [M.R.D.]

1. Flechsig's Opium-Bromide Cure (Ziehen's Modification). E. MAYER.
2. Treatment of Nervous Diseases in the Family. R. GNAUK.
3. Treatment of Septic Infection Emanating from the Uterus. ABEL.
4. The Sensitiveness of Simplified Modifications of the Phenylhydrazin Test for Identification of Sugar in the Urine. A. KOWARSKI.
5. The Medicolegal Treatment of Border-line Diseases Together with Some Remarks on Diminished Responsibilities. A. CRAMER.

1.—The treatment consists of routine administration of opium and the bromides, a very careful diet and cold water treatment. Ziehen emphasizes that the bromides should be given in large doses for about one year. The author believes that the paroxysms are diminished in number and that both bodily and psychic conditions are improved under this treatment. [M.R.D.]

2.—Gnauk discusses the distinctions that are to be drawn in the treatment of nervous diseases in the family and outside of the same. The author believes that in cases in which there are no demonstrable causes, the term "functional" should be avoided. Function is affected in all nervous disorders, and therefore the term functional is not a proper one for purposes of differentiation. There exists between health and nervous diseases the somewhat indefinite conception of **nervousness**. Individuals are frequently seen who show objective signs of nervous disorders like the so-called hysterical stigmata, but who feel healthy and are not incapacitated. The treatment of nervousness is doubtlessly no less important than the treatment of the diseases which may result in consequence of neglecting this condition. The author believes that there are cases which are especially adapted for home treatment, among these being patients who have remained too long in an institution and have accustomed themselves to this form of existence. In these cases, while the disease may have been somewhat checked, the improvement nevertheless did not continue above a certain level, since the pathological condition, as it were, accommodated itself to the conditions and environments of the institution. Furthermore, there are individuals who possess an unconquerable antipathy towards institutions. To this category also belong cases of nostalgia. In no form of disease is uninterrupted contact with the physician of such importance as in nervous disorders. The attention that the physician pays to the treatment of symptoms is often fruitful of astonishing results. This is particularly the case in treating individual organs like the stomach, pelvic organs as well as internasal conditions. Remedies will frequently have to be employed which in other individuals with the same symptoms would not be necessary. [M.R.D.]

4.—The author claims that his method is of value in routine practice. It consists of the following: Five drops of pure phenylhydrazin and 10 drops of strong acetic acid are agitated in a test-tube. To this is added about 1 ccm. of a saturated solution of sodium chlorid, which causes the mixture to assume a thick consistency. Two to 3 ccm. of urine are then added and the whole mixture heated for no less than 2 minutes; by allowing it to cool slowly a yellow precipitate consisting of the typical phenylglycosazon crystals will result. The rapidity of precipitation depends upon the amount of sugar contained in the urine. When the sugar present exceeds 0.2% the precipitate forms in a few minutes; when less sugar than this is present 5 minutes to half an hour will elapse before the reaction is complete. This is a very sensitive test and permits of the detection of even less than 0.1% of sugar, according to numerous experiments made by the author. [M.R.D.]

Revue de Médecine.

7. Gastric Crises and Syringomyelia. R. PAULY and R. POULY.
8. The Origin of the Leukocytes in the Marrow of Bone in the Normal State and in the Infectious. O. JOSUÉ.

1.—Gaucher has classified the **pigmentary dystrophies of the skin**, according to their etiology, as follows: (1) Viteligo with nervous etiology and nervous pathogenesis, symptomatic or trophic viteligo, such as the pigmentary cutaneous changes of diseases or lesions of the nervous system; (2) pigmentary dystrophies with toxic etiology and nervous pathogenesis. This class includes (a) the hyperchromias of toxic origin, of which arsenical melanoderma is the type; (b) the cutaneous achromias and dyschromias of toxic-microbic origin, such as the leukomelanoderma of syphilis and the white patches of leprosy; and (c) true viteligo, of autotoxic origin, in relation with a previous disorder of nutrition. [J.M.S.]

2.—The article will be abstracted when finished.

3.—**Subcutaneous injections of artificial serum** have a considerable action on the condition of the blood and their repetition produces a marked anemia. Labbé, from a study of 24 cases, concludes that the blood of the newborn contains a higher percentage of **oxyhemoglobin** than the blood of the adult. In healthy infants the blood contains from 15% to 16% of oxyhemoglobin. This proportion diminishes during the first 10 days of extrauterine life to 14%. The blood always contains a high percentage of reduced hemoglobin. The various pathologic conditions in the nursling have a less marked influence on the quantity of oxyhemoglobin than upon the weight and the temperature; for example, in enteritis the loss of liquids by diarrhea and vomiting is very considerable and thus produces a relative concentration of the blood and the oxyhemoglobin is reduced in small proportion or not at all. In children who have been submitted to treatment by the subcutaneous injection of artificial serum, particularly when these injections are prolonged beyond 20 days, there is, in spite of a marked improvement of the general condition and a rapid increase of weight, a progressive diminution of the quantity of oxyhemoglobin. This constituent of the blood may suffer a reduction of as much as half its normal amount, so that it is present in about 8 or 9%. On this account the child presents a pallor of the skin which appears at first sight to be pathologic. This diminution of oxyhemoglobin is not due to the reduction of the red blood-corpuscles, because these elements are not altered by a 0.7% solution of sodium chlorid when the proportion mixed with the blood does not exceed one-fifth. The cause of the change should be sought, then, either in the dilution of the blood, which is incompletely compensated for by the osmotic phenomena between the blood and the lymph; or in the exhaustion of the hematopoietic organs which have been overworked by the task that the artificial serum imposes upon them. The appearance of this progressive anemia indicates that it is best not to prolong the injections too far in children. [J.M.S.]

4.—From his studies of **heroin**, Morel-Lavallée concludes that that drug may be used in all cases in which morphin is indicated, because the former has an antialgic power almost equal to, and a hyperogenic power superior to that of the latter drug. Heroin lacks the greatest inconvenience of morphin, namely, that of producing the agreeable sensations that follow the injection almost immediately, and which incite the patient to use the drug for the pleasure of the thing, even after his pain is cured. Heroin controls pain well, but without that wonderful quickness that is char-

acteristic of morphin; the disappearance of suffering is progressive, relatively slow, and is often accomplished without the patient being conscious of the fact; then no **euphoria** replaces the pain after the injection. There is nothing, in fact, holding out an inducement to the patient to repeat the dose of the drug, and no one will ever become a heroinomaniac. Heroin, in small doses, and kept up just below the somniferous dose, produces without euphoria or any temptation to replace one form of intoxication by another, a sensation of warmth that pervades the entire being and, in the morphinomaniac who feels the need for the drug, stops the enervation and the gnawing of the cold depression; whilst the supporting ration of morphin permits of this result only by increasing the amount, heroin produces the result, at least for the small morphinomaniacs, without giving rise to a necessity for increasing the dose. The therapeutic dose remains in all cases below the narcotic dose which, on account of the profound sleep that the new alkaloid determines, is a guarantee against the danger of poisoning. In the serious question of the **treatment of morphinomania**, it is a true progress to have found the means of doing away with the slow method of suppression by doing away at once with morphin without the knowledge of the patient and continuing the supporting rations of hypodermics with identical effect, except that the euphoria does not accompany the injection. [J.M.S.]

5.—Remlinger has studied the **pleurisies that complicate typhoid fever**. He reports 8 cases. These attacks of pleuritis are almost always caused by the bacillus of Eberth, and the pleurisies due to the microorganisms of secondary infection are the exception. The effusion may be serous, hemorrhagic, or purulent. A serous pleurisy preceding the appearance of mild typhoid fever, or even of an attenuated typhoid fever only manifested by an embarrassment of the gastric functions, is a distinct morbid entity. The author calls this pleuro-typhus. The prognosis of the pleurisies that appear in the course of typhoid fever depends upon the character of the effusion; if the effusion is purulent, the prognosis is grave. The purulent infection of the effusion depends upon the period of the appearance of the fluid; a pleurisy appearing late is apt to be purulent. Whether the effusion is serous or purulent, it offers considerable resistance to absorption. In one case the effusion persisted for 75 days. The most interesting peculiarities of these pleurisies are their usual involvement of the left side, their subacute evolution, and their tendency to become sterile by progressive attenuation of the virulence and then by the complete disappearance of the bacilli of Eberth. A very interesting class of pleurisies due to the typhoid bacillus is that in which the pleural lesion results as a secondary infection in the course of some other disease. In 2 published cases a pleural effusion containing the *Bacillus typhosus* developed in the course of tuberculosis. This particular point in the history of pleurisies due to the bacillus of Eberth merits special study. A tabulation of 23 published cases, in addition to those reported in the body of the paper, is given. [J.M.S.]

7.—R. Pauly and R. Pouly (Pauly) publish the history of a case that shows the possibility of the occurrence of **gastric crises** in the beginning or in the course of **syringomyelia**. This is a new point in the relation between syringomyelia and tabes. The patient was a man, 40 years old, who presented lightning pains, gastric crises, and an osteoarthritis of the right foot. The diagnosis of syringomyelia was made from the absence of the sign of Romberg, the Argyll-Robertson pupil, the exaggeration of the knee-jerk on one side and its normal character on the opposite side, preservation of sensibility to contact, disorders of the sensation of pain, and thermo-anesthetic troubles in the lower extremities. If these latter symptoms had been reversed the diagnosis would have been more difficult. [J.M.S.]

8.—Josué has found that in the infections the **bone-marrow** plays an extremely important role in the production of **white blood-corpuscles**. The normoblasts are not concerned in the formation of leukocytes, being only interested in the production of red cells. By histologic methods the author has demonstrated all varieties of leukocytes, except the lymphocytes in the marrow, in uninterrupted series from myelocytes through the stage of large mononuclear leukocytes to the polymorphonuclear forms. It should be remembered that the polymorphonuclear forms

are augmented in the majority of the infections. The experiments also show that the products of the growth of the staphylococcus have the power of starting the leukocytopoietic activity of the bone-marrow, thus explaining the curious reaction that even a circumscribed suppuration produces in the bone marrow. It seems not to be the nervous system that determines the reaction, but rather that the products of microorganismal growth act directly on the bone-marrow after reaching it through the blood-paths. [J.M.S.]

La Semaine Médicale.

January 2, 1901.

1. On the Medical Treatment of Hepatic Colic with a View of Preventing Recurrence. M. A. CHAUFFARD.
2. Evolution of Medical Doctrines of the Nineteenth Century. LÉON CHEINISSE.
3. The Occlusion of the Superior Mesenteric Artery at the Junction of the Duodenum and Jejunum.

1.—Chauffard mentions the relative frequency of cholelithiasis in private practice among the better classes and its comparative rarity among the hospital cases. He criticises the fact that most physicians rest content when they have allayed the acute suffering of the **hepatic colic** without proceeding systematically to treat the case medically with a view to its complete cure. He deplores surgical intervention, remarking that while the cure may be attained temporarily, the same conditions exist for the formation of additional calculi. He thinks the chief factors which should be considered in any proposed treatment must include efforts to check the reflex excitability of the gallbladder, to prevent the formation or increase of gallstones, to increase the biliary circulation by rendering the bile more fluid and more abundant, to maintain the bile in an aseptic condition. He believes these conditions may be met medically, but that prolonged treatment must be instituted to insure success. The treatment should be interspersed with frequent periods of cessation of medication. He places **salicylate of soda** in the first rank as meeting the indications outlined. The drug should be administered carefully, in doses of from 1 to 2 grams per day. The condition of the kidneys must be watched and the cumulative effect of the drug borne in mind. Frequently Chauffard adds a gram or two of **Carlsbad salt** to the treatment. This treatment should be rigorously followed for 9 or 10 days consecutively of each month and continued for many months. He believes it will only be by long-continued use that the permanent cessation of the attacks may be brought about. He has also found **Harlem oil** of great value as an adjuvant to this treatment. He advises the alternation of the **benzoate** with the **salicylate of soda**. Alkaline baths, exercise, massage, and careful attention to personal hygiene are very important. He appends the history of 2 cases illustrating the gratifying results of this treatment. [T.L.C.]

3.—In the superior portion of its insertion to the vertebral column the mesentery crosses the third portion of the duodenum, with the result that in this last portion a loop is formed and the tension is increased by the presence, at this level, of the **superior mesenteric artery**. Occlusion of this artery is not a common condition. The author has collected 24 reported cases. It is probably dependent upon some anomalous condition, and the tendency to occlusion seems to be increased by a weakened physical state. It has occurred during the simple administration of chloroform, when no operation has been undergone. Ptoisis of the intestine increasing the mesenteric tension, and acute dilation of the stomach, as well as vague nervous derangements, have been said to produce the condition. The general symptoms would be those of high obstruction generally. The persistent vomiting would remain bilious in character and not become fecal. Constipation, as a rule, is absolute, following, perhaps, one passage of feces which was present in the lower bowel. There is considerable hypogastric tympany; no fever; a pulse ranging as high as 120. The measures for relief are at first simple. The patient is placed either in the knee-chest position or lying flat on the abdomen. Absolute diet is insisted upon. Rectal nutrient enemata may be employed and gastric lavage practised. These measures failing, **gastro-enterostomy** is our last resource. [T.L.C.]

Original Articles.

SCURVY, NOT RHEUMATISM,

With a Report of 16 Cases of Infantile Scurvy.*

By J. P. CROZER GRIFFITH, M.D.,

of Philadelphia.

Clinical Professor of Diseases of Children in the University of Pennsylvania.

Of all the diseases of infancy, that denominated "infantile scurvy" is, in most instances, one of the easiest to recognize as it is to treat. In a few, however, it offers considerable difficulties, and in some it seems to be one of the stumbling-blocks of physicians who have seen either little or nothing of the affection. This is generally because the symptoms simulate at first other affections, particularly rheumatism. On this account it may be of value to detail the following 16 cases, all of them seen within little more than 18 months, and 9 within 6 months before the date of writing this report. Most of them illustrate the likeness to which the title of the paper refers and the mistakes which have arisen. In a few the diagnosis offered no difficulties.

CASE 1.—A lady from Wilmington was one day telling me of the serious attack of rheumatism her little grandchild was experiencing under the care of homeopathic physician of that city. The little girl had for weeks been suffering severe pains, especially in her legs, and had not improved in spite of treatment. I felt free to say in response to her anxious questions, "Mrs. —, I cannot tell you positively what your grandchild has, but I feel practically sure it is *not* rheumatism."

On June 1, 1899, the child was brought to me, and the following history given:

Marion B., 18 months old. Though delicate originally, she had been in good health for months. The feeding had been varied: Malted milk for the first few weeks of life, then Reed & Carnrick's food, next Robinson's barley, and finally Imperial Granum. The latter had been commenced in September, 1898, and continued for the 9 months preceding the time of examination. It was boiled in water and then mixed with milk, which had been scalded only, no prolonged heating being used. In the last part of March, 1899, the child, then 16 months old, developed pain in lifting the right arm. This soon disappeared, but returned. Next her legs grew painful. Early in May the gums of the incisor teeth, especially of the lower jaw, became swollen and red and bled easily. A change in diet at last was ordered by the physician, who now probably suspected that his earlier diagnosis of rheumatism had been incorrect. She was already somewhat better when I saw her.

A necessarily hasty examination showed the child very pale, and with the gums slightly affected. The treatment ordered consisted of orange juice, raw milk, beef juice, the withdrawal of Imperial Granum, and, later on, the giving of eggs, oatmeal, and a more extended diet. Improvement was very rapid.

One must remain in doubt here regarding the cause of the disease. It is possible that the too early and free use of cereal food may have had some influence, though I am by no means sure of it. Perhaps the child had required a more varied diet.

CASE 2.—Mr. C., of one of the neighboring towns of New Jersey, asked me to visit his child, which I had treated about 6 months before. He stated that the baby cried nearly all the time, night and day, and that it appeared to have rheumatism in its legs. The physician in attendance had been unable to reach a positive diagnosis, but inclined to rheumatism, and had treated for this.

The child was seen on April 10, 1899. Its history and appearance were as follows:

James C., 14 months old. He had been plump and hearty, and never ill, except for a curious convulsive condition when about 7 months old. He had been fed on Malted Milk, except for a very brief interval, until November, 1898, when Just's food with sterilized milk was substituted. About February 1, the gums became sore, and about 3 weeks later both knees became swollen. The child lost strength and weight, and often cried as though in pain. Finally, he cried most of the time, and grew unable to straighten his legs. There had been some bleeding of the gums.

Examination showed a pale but well-nourished baby. While sitting he kept the legs flexed and hanging downwards as though paralyzed, giving much the appearance of the paralysis of a poliomyelitis. There was some tenderness of the knees and a distinct enlargement of the right tibia. The gums of the incisor teeth were red and swollen. The head was slightly rachitic and a rickety rosary was present. The diagnosis of scurvy was clear.

I ordered the administration of orange juice and beef juice, the withdrawal of Just's food, and the use of raw milk. Improvement was immediate. The constant crying stopped almost at once, and in a very few days all pain, pseudoparalysis and redness of the gums had vanished.

Here, again, it appears that a dietetic error was certainly the cause of the disease, but the exact nature of this is uncertain. The simulation of rheumatism on the one hand and of paralysis on the other, was very striking.

CASE 3.—"Doctor," said Dr. —, as I met him at a suburban railroad station, "I have a puzzling case I want you to see. The child appears to have rheumatism, but I wanted to ask you whether this is not a very uncommon disease in infancy."

I replied that it certainly was so in my experience. Making a mental "snap diagnosis" I presently asked: "How are the child's gums?" Hearing that they had been very much inflamed, the diagnosis of scurvy now became very probable.

At the house the following clinical history and results of examination were obtained:

Rosemary MacN., 1 year old, seen May 6, 1899. She had suffered from malnutrition in the early months of life, but later became plump and hearty. She had been fed on Mellin's food and sterilized milk. About 6 weeks previously the left knee became painful, and then the right. Very soon the middle of the right thigh grew thicker and was painful when touched. Only for the last 2 weeks had the gums been swollen and purplish. Quite recently there had been some pain in one arm. Antirheumatic treatment had been given without effect.

Examination showed the right thigh swollen and hard. There was no involvement of the joints. The knees were flexed most of the time. The child let its legs hang as though they were paralyzed. The gums of the upper incisors were swollen and deeply purple-red.

I gave it as my opinion that the baby had scurvy, with which the attending physician entirely concurred, saying that he felt as though "scales had fallen" from his eyes.

The child was ordered raw milk, Mellin's food was withdrawn, and orange juice prescribed. Pain disappeared and health was regained with very great rapidity.

Dietetic error was clearly the cause in this case also. Whether this was due to the use of Mellin's food or to the sterilization of the milk cannot be definitely determined.

The following case of scurvy, occurring in Germantown, is of interest only from an etiologic point of view. Dr. Th. C. Potter, with whom I saw it, had already made the diagnosis.

CASE 4.—Roland F., 9 months old, seen February 19, 1900. The child had been healthy and well nourished. He had been fed on Mellin's food, with which was mixed milk and water, which was heated but not quite to boiling. About 4 weeks before seen by me he developed fever and great pain when his right leg was moved. No swelling could be found at that time. This condition continued about 36 hours, and

* Read at the meeting of the Philadelphia County Medical Society, December 26, 1900.

afterwards appeared intermittently, lasting a couple of days at a time. Finally it developed more persistently, accompanied also by edema, and last by involvement of the gums.

Examination showed the right leg and thigh edematous and somewhat painful on passive movement. It could not be determined whether the tibia was thickened or only the soft tissues affected. The gums of the upper incisors were quite swollen and purplish.

The child was put upon orange juice, Mellin's food was withdrawn, and the milk not heated above body heat. Recovery was very rapid.

In this case we can at least exclude any deleterious action of prolonged high temperature upon the milk, since this was at no time employed.

The intermittent nature of the pain as often seen in this disease is also well exemplified.

CASE 5.—The next case is one of peculiar interest from the fact that it was brought to the Surgical Out-patient Department of the Children's Hospital, on account of pain in one hip, which rendered the diagnosis of hip-joint disease probable. Dr. Jopson carefully examined it there for the existence of coxalgia, and decided to apply an immobilizing dressing as a provisional measure. This was worn for some days, the child meanwhile visiting the dispensary once or twice. Finally, at its visit on May 19, 1899, the other hip was also found to be painful. Dr. Jopson then decided that the affection was scorbutic and referred the case to the Medical Department, where the following history and examination were obtained.

George T., 13 months old. He had been fed on condensed milk for the first 4 months of life; next on Mellin's food until 8 months old; and since then on Malted Milk. He thrived indifferently well, but for 5 months sweating had been profuse. He had been very fretful recently.

Examination showed the child plump and of good color, with no osseous symptoms of rickets, except slight beading of the ribs. Movement at both hip-joints and both knees was very painful. There was no affection of the gums. A slight petechial eruption was present over the dorsum of the feet.

The diagnosis of scurvy seemed very certain. The baby was ordered orange juice, beef juice, and a mixture of milk and water which was to be scalded. In a very few days he had evidently much less pain, and could move the legs more freely. The eruption was disappearing. In a few days more the symptoms of scurvy had entirely vanished.

It is clear that sterilized milk was not an etiologic factor in this case, since no milk was added to the Horlick's food. In fact, the use of scalded milk was one of the therapeutic means employed in the treatment of the disease.

CASE 6.—The next case was a child of a physician and had been under my care. I can offer no excuse for a failure to make the diagnosis earlier than I did.

Joseph C. A., born March 28, 1898. He had been a healthy, well-nourished child, and had been thriving for months on a sterilized mixture of cream, milk, and water, with dry malt extract. When 7 months old, he was exposed considerably on a river trip and, a few days later, just before the end of October, he became cross and fretful, and lost his appetite to some extent. For the last 3 days he would cry out suddenly while in the arms, as though afraid or in pain. The pain seemed to be situated chiefly in the legs.

Examination by me on October 31, 1898, showed a large, fat child, with slight beading of the ribs. Forcible extension of the right leg made the child start and cry. No swelling or redness could be discovered anywhere. There was no affection of the gums. The 2 lower incisor teeth had been cut.

The history of exposure made me underestimate the possibility of scurvy, and I made a provisional diagnosis of rheumatism of the right knee, and asked the father to report in a few days.

The report did not reach me, however, until nearly a month later (March 23). The child had continued fretful and with pain in the right leg. For a few days he had had pain in the other leg also, and had seemed unwilling to move

either of them. Passive motion of them often gave pain. There was some sweating of the head. About a week ago the upper gums in front looked like a "blood blister" but this had improved.

I at once made the diagnosis of scurvy, and visited the child the next day. Examination then showed the gums of the upper incisors swollen and a little red; no discoverable swelling of the tibiae, some beading of the ribs.

I ordered orange juice, the withdrawal of malt extract, and the stopping of all cooking. In 2 days the pain was nearly and in 5 days more, entirely gone.

It is impossible to be sure in this case whether the scurvy was due to the addition of malt extract or to the sterilizing of the milk, or to some other cause. I was unwilling to make a therapeutic test to determine this.

CASE 7.—The following case was interesting on account of the long continuance of the attack, about 6 months in all, and of the difficulty in diagnosis which it presented. The attributing of pain to a trauma is worthy of note.

The case occurred in the family of a prominent resident of Easton. The father called upon me on June 14, 1899, to talk over the condition of his child, the nature of whose ailment had not, he said, seemed clear to several physicians who had been in attendance at different times. One had insisted that the child must have had a fall, while others suggested the possibility of rheumatism. From the father's description of the symptoms, I felt it extremely likely that the case was one of scurvy. Two days later I saw the child and obtained the following history and examination:

E. D. W.; 16 months old. His nutrition had at first been very poor, and he weighed but 9 pounds at 4 months of age. At that time he was taking Eskay's food and sterilized milk. Later different foods were tried, such as Horlick's, Mellin's, and egg albumen. Finally a return to Eskay's food was made and this diet was continued. About February 1, or late in January, the child, being then about one year old, suffered from swelling and tenderness first of one knee, and then of both. He could not use the legs at all. Next one arm became painful. The pain in the arm was intermittent, and to some extent that in the legs also. Beef juice was commenced in February and continued until warm weather began. During February and March he lay on his back with his feet drawn up and making very little movement of his legs. In April and May he was better and had very little trouble except for a short relapse in April. About the end of May he grew much worse. For about two weeks before he was seen the gums had been "congested." On May 31 he had nosebleed and developed an ecchymosis about both eyes, giving the appearance of a large bruise. The gums bled on June 8. Since then they had been purple. Severe nosebleed occurred on June 7, and from this time the child had been pale, languid, and weak, unable to sit up, and had edema, rapid respiration, loss of appetite, a poor digestion, and rather frequent vomiting.

Examination showed a child fairly well nourished but looking very ill, quite anemic, and with the legs and feet very edematous. Every touch of them elicited cries of pain. Movement of the arms was painful. The ecchymosis of the eyes had disappeared, no subperiosteal swellings were discoverable in the arms and legs and no petechiae found. The gums of the upper incisors exhibited a slight purplish tint. The fontanelles were opened, the ribs beaded, the epiphyses of the wrists enlarged.

In the way of treatment, there was ordered the juice of one orange daily, one ounce of beef juice 3 times a day, the withdrawal of Eskay's food, the giving of equal parts of milk and water which should be pasteurized at first but raw after a few days, the administration of iron, and the removal to the seashore. This treatment was commenced at once, the child being taken to Atlantic City on June 19. On June 21 he was able to sit up and by June 22 all evidences of pain had disappeared. Ten days later all edema had vanished, the color was returning and the child was playing. The after-history is uneventful. The symptoms of scurvy remained absent and the rickets slowly disappeared under treatment and in 6 months was nearly gone.

The diagnosis in this case was clear. The prognosis

was somewhat uncertain at first owing to the very greatly impaired strength of the digestion, the marked anemia and the edema. The result, however, was brilliant, as it usually is in this disease.

CASES 8 AND 9.—In March, 1900, I received a letter from a physician asking me to see with him a case of rheumatism in a baby living in Germantown. Before we reached the house, he told me that he had used antirheumatic treatment in vain, and that he was beginning to suspect the existence of scurvy. In fact, he had recently ordered fruit-juice and vegetable soups, which, however, we found that the mother had not given, as the diet seemed to her unreasonable.

In the diagnosis of scurvy I entirely concurred after seeing the child—or rather the children, for the interesting feature is that we had here scurvy occurring in *twins*. One of these cases was, without exception, the worst I have ever seen. The history is as follows:

CASE 8.—Wallace McC., aged 13 months, visited March 25, 1900. The child had been fed on Mellin's food with sterilized milk from the age of 5 months. About 11 weeks before seen by me the gums had become purple. About 3 weeks later pain and edema developed in one leg below the knee and then extended to all the extremities. The child had become unable to move its legs in the slightest degree. There had been profuse sweating. The condition of the arms had later improved considerably.

Examination showed an anemic and evidently ill and suffering child. He lay helpless on his back with his legs extended and swathed with cotton and wrappings. He was bathed in perspiration and wet with urine, for pain on motion was so great that moving, dressing, or changing of the child seemed almost impossible. He was indeed a pitiable object. Both legs and both thighs were greatly swollen throughout. Subperiosteal thickening of the tibiae was easily discoverable and there was distinct thickening and tenderness of the right clavicle. Slight beading of the ribs was present. The fontanel was nearly closed. The gums of the incisor teeth were somewhat swollen and red.

He was ordered orange juice, beef juice, and cod-liver oil with iron, and the use of raw milk without Mellin's food. Improvement was rapid, and in about a week pain had practically disappeared.

CASE 9.—The twin brother, Lansing McC., had been fed in a similar manner and developed the disease at the same time, 11 weeks before I saw him. The first symptoms were redness of the gums as in the other case. After 3 weeks—as in the first case—pain developed in the legs and arms. This had, however, been much less severe than in the brother and had later disappeared. He had never been incapacitated by it.

Examination showed a well-nourished child with a pasty, anemic appearance. The gums were swollen and very red. There was no discoverable pain or edema anywhere.

The treatment ordered was the same as in the last case and the improvement was as rapid, although not, of course, as striking, since the condition was so much less grave.

These 2 cases are extremely suggestive. It is a curious fact that the disease developed at the same time in both children upon food which was not different from that used for months, and which had apparently agreed perfectly. The reason for this we can hardly understand, unless we assume the existence of an infection, and for this we have hardly sufficient ground. Again, it is interesting to note that whereas the symptoms in one brother ran to edema and subperiosteal involvement, in the other the chief characteristics were the marked anemia and the affected gums.

CASE 10.—The following case is to me extremely interesting from the point of view of the causative influence of food.

Lawrence MacE., 8 months old when seen first on January 27, 1900. The child was a wretched, marantic specimen, always suffering from indigestion and diarrhea. He had been fed for the first 2 months on the breast and bottle, then

solely on Malted Milk, and then on condensed milk. When 5 months old he was placed upon barley water and white of egg for 2 months and, finally, for the last month upon Mellin's food. When first seen he exhibited some edema of the feet and of the cheeks. Involvement of the limbs and of the gums was looked for, but not found. I started the child upon raw, laboratory percentage milk, which contained barley water and a very low proportion of proteids and of fat.

On February 19, 1900, before circumstances had permitted more than a very slight increase of the percentages, the gums of the upper incisor teeth were found to be swollen and very purplish. Orange juice was at once ordered and continued, and the symptoms of scurvy rapidly disappeared. No immediate change was made in the food, although later, and as soon as the digestive power improved, the percentages were raised.

It is impossible in this case to determine whether the disease began to develop when the child was upon Mellin's food, as indicated by the edema, or whether the involvement of the gums marked the onset of the disease, which was then to be attributed to the very low percentages of the milk mixture. It is to be noted that a certain small amount of starch in the form of barley water was present in the food ordered, but that there was no cooking of the food whatsoever. I am inclined to view the edema as the earliest symptom.

CASE 11.—The next case illustrates, as many of the others have done, the simulation of rheumatism by scurvy. It also illustrates the development of scurvy independently of any heating of the food, and upon nourishment which seemed perfectly suited in every way.

Emily J., first seen when 4 months old. She had been a fairly healthy child, and was well-nourished, although not gaining much weight. None of the various methods of feeding previously tried had agreed well. I placed her on a raw low-percentage mixture of laboratory modified milk with barley water. This agreed nicely, and the weight steadily increased. By the middle of March, 1900, when 6 months old, she was the picture of perfect health, jolly, rosy, plump. She was now taking a mixture of fat, 3.75%; sugar, 7%; proteid, 1.50%.

In April the child lost appetite, was fretful, and ceased to eat much or to gain in weight. The fat percentage was tentatively reduced to 3.50%, and finally to 3%, owing to continued indigestion. About the first of May she commenced to have pain in the legs, only discovered when they were handled in a certain way, and apparently situated somewhere about the ankles. There was still no gain in weight, owing apparently to the occurrence of a sharp bronchitis with fever. She grew pale and had continued signs of indigestion.

Examination on May 18, at the age of 8 months, discovered pain on passive movements of the legs and indisposition to active movements of them. There were no swellings, edema, or affection of the gums. The child had cut no teeth.

The diagnosis of incipient scurvy was made and the child given orange juice, beef juice, salt baths, oil massage, and, later, codliver oil internally. The 1.50% of proteid was increased to 1.75. The mixture was pasteurized and barley water was stopped.

In a week the pain had practically gone, and the child had begun to increase in weight. By the end of May she was doing well, and the percentages in the food were now increased to fat 3, sugar 7, proteid 2.25.

What is most interesting about this case, apart from the simulation of rheumatic pain, is the fact that the scurvy developed on a mixture in which no heat was employed and in which the percentages seemed to have suited admirably. I am inclined to think, however, that possibly a still greater increase of proteid was needed; yet it is to be noted that recovery began after a very inconsiderable increase, .25%, of the proteids was made, which seems to show that the orange juice was the curative agent. It is conceivable that the barley water may have been an etiologic factor. Pasteurization

was commenced after scurvy had appeared and was continued on account of the weather being quite warm, and for fear that changes might be taking place in the food.

CASE 12.—The following case is like the last in that the cause of the attack probably consisted in a deficiency in the amount of proteids. Yet this is not certain.

Mary C., 3 months old when first seen, December 29, 1899. The child, always bottled-fed, had never thriven in spite of various changes in her diet, and was a feeble, emaciated specimen with extremely weak digestion. I gave her a pasteurized low-percentage laboratory milk with barley-water, and gradually increased this in strength. The child meanwhile did remarkably well, and by the end of June, 1900, being then 10 months old, had gained 7 pounds in 5 months. By this time the percentage strength equalled, fat, 3; sugar, 7; proteids, 1.25. For 2 weeks the child seemed to have pain when the chest was grasped or the legs moved. Orange juice was given for 3 days, and the pain diminished, but as this seemed to produce diarrhea it was stopped. A little later the proteid percentage was raised to 1.50, and then to 1.75. As this caused diarrhea it was again reduced to 1.25. About the end of July pain returned in force. The child was so tender all over that it would move no more than its head, and its cries, when touched, were pitiable. There was never any discoverable swelling of the limbs or affection of the gums. Orange juice was again given, and in less than a week all pain had gone completely.

The laboratory milk mixture in this case had been pasteurized from the beginning, and was still so during and after the attack of scurvy. The heating of the food may therefore probably be dismissed as an etiological factor. As stated, it seems most likely that the cause was a low proteid proportion.

CASE 13.—This next case is very like some of the preceding in its simulation of rheumatism, and like 2 others in that the possibility of the influence of trauma had been entertained.

Towards the end of June, 1900, a medical friend asked me about his baby of nearly a year who, he thought, was suffering with rheumatism. Yet, he said, he was not sure, as he had always understood that rheumatism was unusual in infants. He had thought, too, of neuritis, but had excluded this. I suggested that the affection was probably scurvy, and urged that he give orange juice and change the diet. On June 27, the father sent me a full account of the case, which I abridge:

The child was 11 months old. He had been fed since the second or third month on a scalded mixture of cream, milk, and water, with Eskay's food added. He had always been healthy and fat, but had no teeth. The first symptoms of scurvy were manifested early in June. The child did not move its legs nearly as freely as formerly, seemed to have pain somewhere, and would no longer make an effort to stand when held upon his feet. There was no swelling of the legs. The nursemaid was very careless, and it was feared that at some time the baby had had a fall. It was also thought that the baby might have taken cold from a careless use of damp diapers. Careful examination showed the right ankle tender when the foot was move passively, and, after a few days, the left limb also, at some of the joints. The child did not move its limbs willingly. The upper extremities were never affected. Salicylate of cinchonidin was commenced in small doses, and Eskay's food discontinued. Improvement within a day or two was very great. The salicylate was given only for 1 or 2 days, and then replaced by orange juice. Within 2 or 3 days after orange juice had been started all pain disappeared, and the child moved its limbs as freely as it had ever done.

The salicylate may have had an analgesic action, although certainly not a curative one; but it is very possible that the stopping of the Eskay's food was the chief therapeutic factor. The milk mixture had been scalded previously, and this was not stopped later.

CASE 14.—This case is still another instance of the mistaking of scurvy for rheumatism.

I was asked by Dr. F. B. Gummey, of Germantown, to see with him a little patient of his, who was being treated unsuccessfully for rheumatism in one of the New Jersey seaside resorts. He believed the disease to be scurvy, and had advised antiscorbutic treatment, but the local physician still could not abandon his earlier diagnosis of rheumatism. On July 13 I saw the case with both physicians, and concurred in the diagnosis of scurvy. The history and result of the examination were as follows:

William F., aged 9 months, had never been ill previously. He had always been fed on a sterilized milk-and-water mixture. About 2 weeks before seen he developed a widespread eczematous eruption, fever, pain on movement, and slight redness of the gums. This condition continued, with some irregularity of the bowels and evidence of impaired digestion. Except that grasping the child's chest seemed sometimes to give pain, the suffering soon centered itself in the legs, and was intermittent. Swelling of the lower extremities soon developed. There had been considerable sweating.

Examination showed an exceptionally hearty and well-developed child. The lower extremities were edematous, especially the legs and feet. No subperiosteal thickening could be discovered, nor any distinct involvement of the joints. The child was unwilling to move its legs, and passive movement gave pain. The gums were red, but not swollen or actually purple. There were 7 teeth, the fontanel was of normal size, and there had been but slight beading of the ribs. Orange juice and beef juice were ordered, and sterilization was stopped. Recovery was prompt.

In this case it appears very probable that the sterilization of the food may have been the cause of the disease, yet this is not certain.

The last 2 cases show the existence of hematuria as a prominent symptom of scurvy.

CASE 15.—As in Case 6, I admit that I failed to make an early diagnosis; in fact, was misled entirely as to the real nature of the malady, and even later could not for some time make myself believe that it was really scorbutic. The case was a most perplexing one and the possibility of scurvy being present was by no means forgotten. The history is as follows:

Richard P., born July 22, 1899. The child was fairly well nourished, though decidedly below weight and having a tendency to sour vomiting. He had been fed constantly on Mellin's food and a very fat milk. On November 15, 1899, at the age of 4 months, he was first put upon raw, laboratory percentage milk, to each bottle of which the mother added a teaspoonful of Mellin's food. The child did well and gained weight, the proportions of fat, sugar, and proteid being increased from time to time as indicated, the fat, however, being somewhat low on account of the vomiting. Possibly due to this fact, some symptoms of rickets developed. The symptoms of rickets soon began to improve decidedly under a stronger diet, and early in February the child looked and seemed remarkably well. He was now digesting a milk mixture of the strength of fat 3.25, sugar 6, proteid 1.25.

On February 17, the baby being then 6 months old and in excellent health, I was sent for hurriedly on account of what was supposed to be an injury of the left arm. The mother strongly suspected that the nurse had hurt the child in some way. The arm had suddenly become painful and the child would not move it. Examination showed no discoverable cause for this. The gums were examined and found normal. By the next day the arm was entirely well and the condition was attributed to a slight wrench or similar cause.

On February 27, 10 days later, the baby became fretful and seemed to be in pain. Although he constantly moved his hands to his ears and pressure about them was painful, yet it was observed that passive movements of the legs also gave pain. The gums appeared normal. By March 3, earache had disappeared and the legs were clearly free from pain. The child now appeared to have pain in the abdomen. The left knee and ankle had become decidedly edematous but were not painful on passive movement. The gums were somewhat swollen but not red. The urine contained a small amount of albumin.

Again suspecting that I might possibly be dealing with scurvy, I ordered the Mellin's food to be omitted from the

mixture. On the next day a sharp bronchitis with fever developed. Movements of the legs caused no pain, and the swelling of the left leg was somewhat less. The urine was smoky in appearance and contained abundant albumin and numerous red blood-corpuscles, but no casts. On the day following, March 5, a minute patch of purplish discoloration was visible on the gums of the lower central incisors, the only teeth. Some pain on moving the legs had reappeared. The diagnosis of scurvy was now very probable, yet it seemed possible that with the severe bronchitis there was some nephritis, which accounted for the symptoms. The child was given the benefit of the doubt, however, and orange juice was prescribed.

Up to March 8 the bronchitis had continued severe, with fever and rapid respiration. The urine was much redder than a nephritis ordinarily exhibits, and there had been no casts found. Owing to indigestion, orange juice was stopped on this date, although the diagnosis of scurvy seemed now beyond question. By March 10, the urine showed very little blood. Recovery from this time on was rapid and uneventful.

The history of this case and the diagnosis are of considerable interest. The first very temporary pain in the arm did not give sufficient ground for a diagnosis of scurvy. Later, the whole course of the scurvy was marked by the existence of the symptoms of earache, severe bronchitis, and indigestion, which rendered the discovery of the degree of pain in the legs extremely difficult. The small purplish spot on the gums was trivial and of later development. In reality it was the hematuria which decided the diagnosis in my mind, and to the examination of the urine I was led especially by the presence of the slight edema.

Hematuria is a not infrequent symptom of scurvy, and sometimes, according to Barlow, the only one. In this case it was the most persistent as far as could be discovered. The case illustrates very well the intermittent character of the pain in the legs, as it so often occurs in this disease.

The orange juice was given for a very short time—only 3 days—and then withdrawn, before the symptoms of scurvy had disappeared. I hesitate to regard it as having had any material influence in the cure of the disease. It would appear more likely that in this case the withdrawal of the commercial food was the sole factor in the cure. It is interesting to note that the milk was not cooked in any way at any time.

CASE 16.—This last case was even more puzzling than the preceding one. The diagnosis was based entirely on the occurrence of a hematuria which resisted other treatment, but promptly and permanently ceased after the administration of orange juice was commenced.

Francis V. W., aged 5 months when first seen by me in November, 1899. The child had been fed in various ways, including laboratory modified milk, but had not thrived, and was a thin specimen of about 9 pounds only, always the subject of severe indigestion. Careful modification of his milk with the addition of barley-water, still done at the laboratory, changed this condition, and he began and continued a steady gain. Finally he reached, at about the age of 9 months, a percentage mixture of fat 4, sugar 7, proteid 150; as large a proteid percentage as it had been possible to use safely, and seemingly sufficient for his needs. The food was always uncooked.

At this time, about March, 1900, I found that he was passing urine of a smoky tint, which stained the diaper, and which contained numerous blood-cells; and on inquiry I learned that a number of weeks before he had had similar urine for about a week, and again, 10 days ago, for a few days. The baby seemed perfectly well in every way.

From now on the blood in the urine was constantly present, and generally to such an extent that the color was distinctly red. The general health began to suffer somewhat, the child losing weight, being fretful, and at times seeming to have pain on urination. This last, however, was uncer-

tain. Poultices were used over the bladder with the idea that there might be a cystitis present. Then hydrastis, and later ergot were tried. Sometimes opium was used, as the child was very restless at night and seemed to be suffering. Later, the evidences of pain disappeared, but no treatment had the slightest influence on the hematuria, which continued unabated. There was never any affection of the gums (there were no teeth), nor any swelling or discoverable pain in the limbs.

The hematuria continued for somewhat over a month, when I concluded that it was probably scorbutic in origin. Orange juice was started with astonishing results. In a few days the hematuria stopped completely and permanently, the treatment with orange juice being meanwhile persisted in. The return to good general health was rapid, and increase in weight recommenced.

I have already called attention to the fact stated by Barlow, that hematuria is sometimes the sole symptom of scurvy. This justified the diagnosis of scurvy in the case just reported. It is of course possible that the bleeding may have been due to a calculus or other cause; but the prompt cessation of the hematuria and all other symptoms with the beginning of orange-juice treatment was almost too startling to be a mere coincidence.

For the development of the disease in this case, I see absolutely no cause unless it be the use of a too low percentage of proteid in the mixture,—a thing which could not be avoided, and which was not changed at all until after the scorbutic symptoms had disappeared.

It is not my purpose to enter into a detailed description of the features of scurvy or even to analyze the cases I have recorded. The striking characteristics of each have already been emphasized. There are only two or three points to which I would like to draw special attention.

It is evident that although the cause of scurvy seems clearly to be dietetic, yet there is no one dietetic fault which can be held responsible. This is the common experience with the disease, and the cases here detailed are but additional proof of it. Oftenest we find that scorbutic children have been fed upon commercial foods, and there seems every reason to believe that these constitute a powerful etiologic factor. The collective studies of the American Pediatric Society, in which, as one of the committee, I was greatly interested a few years ago, put this statement beyond question. In at least one of the cases reported here the simple omission of a patented food from the dietary was followed by disappearance of scurvy.

There are cases on record in which the sterilization of milk has seemed to produce the disease. In my own experience this is not a prominent factor, and I am convinced that its power is overrated. I would call attention to the number of cases in my list in which no heating at all was employed. In none of the 16 is there any absolute proof of the harmful action of heat. Yet it is to be suspected in some of them; and that cooking of the food is capable of producing scurvy seems to be beyond question in some reported cases.

In some of my cases it is probable that the fault lay in the lack of a proper proportion in the different elements of the mixture; oftenest a too low percentage of proteid; but in many cases of scurvy we are entirely unable to discover just what the factor is. It may readily be—in fact it must be—that it varies with different children.

With regard to symptoms, it is most important to remember that the affection of the gums is generally not the earliest symptom and that the disease may exist

without it. Indeed, it is usually absent if no teeth have appeared. Pain somewhere, generally in the legs, is oftenest first seen, and it is due to this fact that so many mistakes in diagnosis are made. So many of my cases bear out the common experience that rheumatism, more than any other disease, is erroneously diagnosed when scurvy is really the condition. Yet we may occasionally have scurvy without pain being a prominent feature. Indeed, although the diagnosis is easy in typical and well-developed cases, and when one has the possibility of the presence of the disease in mind, it is by no means so easy in incipient or atypical cases. One should be far from regarding the failure to make a diagnosis as a reproach to any physician.

Treatment of the disease is most simple, as my case histories and the general experience with the disease show. A proper alteration of the diet and, even without this, the administration of fresh fruit juice, is sufficient to work a cure which seems almost miraculous. Only in cases where debility has grown extreme, or where intercurrent maladies exist which possibly interfere with treatment, need we fear a fatal result. I have had one fatal case, not included in this list of histories, in which the inanition from persistent chronic enterocolitis was so great that the child died;—not, however, of scurvy.

That several of the cases of my list recovered promptly on the use of fruit juices without any change of diet is a noteworthy fact, since in the great majority of reported cases, at least in this country, some alteration of the usual diet has also been made. This is a warning against too quickly altering the food which for certain reasons we have deemed best, simply on the ground that scurvy has developed. A curable scurvy is much to be preferred to a possibly fatal diarrhea or gastritis, the result of a diet which may precipitate these. So, too, with regard to the heating of milk. Even if we suspect that such heating is the cause of scurvy in a certain case, we should not hastily abandon it if we see any good reason for continuing it. Where raw milk can be used safely it is to be preferred.

WHEY-CREAM MODIFICATIONS IN INFANT FEEDING.

BY FRANKLIN W. WHITE, M.D.,

of Boston, Mass.,

Assistant in the Theory and Practice of Physic, Harvard Medical School; Assistant Visiting Physician to Long Island Hospital; Assistant Physician to Infants' Hospital,

AND

MAYNARD LADD, M.D.,

Assistant in Physiological Chemistry and in Diseases of Children, Harvard Medical School.

THE scientific modification of milk in the substitute feeding of infants, like most advances in medicine, has been in the nature of an evolution. The simple dilution of milk with plain water, lime water, cereal waters, or whey, without reference to the resulting percentages of fat, sugar, and proteids, has been generally acknowledged to fall far short of supplying a proper food for infants of different ages and development, and men everywhere have tried to improve upon the older methods. Frankland, as far back as 1854, and later Monti, Biedert, Jacobi, and others have all contributed to the study of the subject, and to them we owe the inspiration of many of our ideas.

The first step of importance in the advancement of

infant feeding in this country was the work of Dr. J. F. Meigs and his son, Dr. A. V. Meigs, of Philadelphia, many years ago. The elder Meigs had observed in a large clinical experience that certain combinations of milk, cream, lime-water, milk-sugar, and water, seemed to agree with the average infant. The younger Meigs undertook to establish a scientific explanation for the successful results of his father's empirical formula. As a result of his investigations he found that the Meigs mixture corresponded closely to his analysis of human milk, especially in regard to the percentage of proteids. He then improved the original formula in certain details so that the mixtures calculated from it were estimated to yield a milk containing 3.50% of fat, 6.66% of sugar, 1.21% of proteids, 0.25% of ash, and 88.25% of water.

This was a distinct advance over the old methods of simple dilution of milk, as it brought to the attention of the medical profession three very important points in connection with the subject of infant feeding: First, that simple dilutions of milk were irrational in that all the ingredients were reduced alike; second, that a milk should be modified to resemble human milk; and third, that the Meigs formula expressed for the first time, though in a limited way, the idea of a percentage basis in the modification of milk.

The development of Meigs' principle of feeding was worked out by Dr. T. M. Rotch, of Boston, who, in 1890, made the pertinent suggestion that all modifications of milk should be expressed in percentages of fat, sugar, and proteids, and that prescriptions for the same should be written calling for precise proportions of the various ingredients; in other words, he propounded the principle of thinking and writing in percentages. This idea led to the establishment, in 1892, of the Walker-Gordon milk laboratories, under the scientific direction of Dr. Rotch, where, in accordance with his ideas, milk could be obtained in a pure condition, and of staple composition, and where it could be accurately modified and dispensed. This system of percentage modification was developed and perfected by Mr. George E. Gordon and Mr. J. H. Waterhouse, under the direction of Dr. Rotch, until the modification of the various ingredients of milk has been elaborated to a degree not conceived of in the beginning, so that at present almost any combination of fat, sugar, and proteids can be obtained.

The work up to this point has been satisfactory so far as the modification of the percentages of fat, sugar and total proteids are concerned, but cow's milk differs from human milk in the proportions of the two kinds of proteids, and a modification that simply reduces the total proteids as a whole without reference to their relative proportions has not gone as far as our knowledge of the chemistry of milk allows.

Koenig's analysis of the proteids of cow's milk and human milk is as follows. No attempt is made to distinguish between lactalbumin, lactoglobulin and other proteids possibly present in whey, and we in our paper shall include them all under the term "whey-proteids."

	Cow's Milk. Percent.	Human Milk Percent.
Caseinogen	2.88	0.59
Whey-proteids.....	0.53	1.25
Total.....	3.41	1.82

According to these figures cow's milk contains twice as much total proteids as does human milk, and we also see that, of the total proteids in cow's milk, approximately $\frac{2}{3}$ is caseinogen and $\frac{1}{3}$ is whey-proteid. In

human milk, on the other hand, we see that approximately $\frac{2}{3}$ is whey-proteid and $\frac{1}{3}$ is caseinogen.

If, then, we prescribe an ordinary modified milk with a total proteid of 1.50% (the percentage of average human milk), we give 0.25% of whey-proteid and too much caseinogen, namely, 1.25%. If we attempt to reduce the caseinogen to 0.50%, the amount present in human milk, we get too low a total proteid. It seems reasonable to suppose that the disturbance in digestion in infants who are being fed on modified milk is due not so much to the chemical differences of the proteids in cow's milk and human milk, as to the excessive proportion of caseinogen to whey-proteids. Whether this be true or not, it is a generally accepted principle that in substitute-feeding we should imitate the composition of human milk as closely as possible.

Backhaus¹ has attempted to modify the proportion of caseinogen and whey-proteids in cow's milk so as to make it resemble that which occurs in human milk. His method, however, involves the partial predigestion of a certain amount of caseinogen by trypsin in order to raise the percentage of soluble proteids in the whey. This whey contains in addition to ordinary whey-proteids 0.5% of peptones. He gives the prescriptions for three mixtures, in only one of which is there any attempt to make the proportion of caseinogen and whey proteid resemble that of human milk.

The credit of calling the attention of the medical profession in this country to the insufficient method of dealing with the proteids in milk modification belongs to Dr. Thompson S. Westcott, of Philadelphia, who, in a monograph on "The Scientific Modification of Milk," published in the *International Clinics*, Vol. III, Tenth Series, drew attention to the differences in the relative proportions of caseinogen and lactalbumin in human milk and in cow's milk. Dr. Westcott gives in his paper certain general formulæ for the calculation of whey and cream mixtures by which the total proteids may be raised without increasing the percentages of caseinogen, by the addition of whey, in place of water, to creams of varying strength.

Koenig's analysis of whey is as follows:

	Per cent.		Per cent.
Proteids.....	0.86	Salts	0.65
Fat	0.32	Water.....	93.38
Sugar	0.49		

It is obvious that it will be impossible to raise the percentage of whey-proteids in a mixture of cream and whey above the percentage in the whey itself, and if this analysis applies to all specimens of whey the percentage in the whey-cream mixture will be lower than 0.86%, probably not exceeding 0.75%. If caseinogen be now added by means of cream and fat-free milk in such a way as to contribute an additional 0.50% of proteids, we shall have a mixture with a total proteid of 1.25%, consisting approximately of $\frac{2}{3}$ whey-proteids and $\frac{1}{3}$ caseinogen, the proportion which occurs in human milk. Higher total proteids can be obtained by increasing the percentage of caseinogen by the addition of fat-free milk, but each increase necessarily alters the relation of the two proteids, so that it approaches that which occurs in cow's milk.

A mixture containing 0.75% of whey-proteids and 0.50% of caseinogen is eminently suited for an infant in the first two or three months of life and for an older infant with disturbed digestion requiring weak and

easily assimilable proteids. It is, however, too low a percentage of total proteids to carry an infant throughout the nursing period, and as the child grows older the caseinogen can be increased until the total proteids are the same in proportion as in cow's milk. In the latter months of the nursing period the management of the proteids is less troublesome and the ordinary modifications, when intelligently used, rarely fail to give satisfactory results.

Westcott's formulas and calculations are based on the above analysis of Koenig. On referring to Bulletin 28, of the United States Department of Agriculture, we find that the average of a large number of specimens of whey as purchased yielded a whey-proteid of one percent, (1.00%). It is evident therefore that there is some variation in the whey-proteids in milk from different sources. It was important to know whether the percentage of whey-proteids in the whey obtained by us from milk was not higher in percent than that given by Koenig and on which Westcott bases his formulas and tables. It also was important to perfect this method so that physicians might send to the laboratory prescriptions for definite percentages of whey-proteids, caseinogen, fat and sugar. Finally it did not seem sufficient to accept the method on mere theoretical considerations, and we therefore undertook, at the suggestion of Dr. Rotch, to compare the coagulability, digestibility and emulsion of whey-cream modifications with other forms of modified milk. In carrying out these experiments we have utilized the conveniences of the milk laboratory where the whey and various modifications have been prepared under our direction, and we wish to acknowledge our indebtedness to Mr. George H. Walker and Mr. J. H. Waterhouse for the many courtesies and aids accorded us.

A preliminary report of the following experiments was included in a paper on "Emulsions, Cereals and Proteids," which was read by Dr. Rotch before the New York Academy of Medicine in the Section on Pediatrics on October 18, 1900.

Method of Making Whey.—The whey is made by coagulating fat-free milk with liquid rennet; about 1 dram of rennet being added to 10 quarts of milk. The fat-free milk was made by separating the fat of whole milk by the centrifugal separator. It is more convenient and economical to make the whey in this manner than from whole milk. The milk was kept at a temperature of 30° C., till the curd formed and the whey was then strained off through muslin and absorbent cotton. In further preparing the whey for use in milk mixtures, it was necessary to heat it to a temperature which would destroy the rennet which had been added, without precipitating the whey-proteids. The rennet enzyme, according to Hammarsten,² is destroyed by a temperature of 60 to 70° C., more or less quickly according to the duration of heating and the concentration of the solution. Lactalbumin, according to Hammarsten, is precipitated by a temperature of 72° to 84° C., so it seemed possible to destroy the rennet by heat without coagulating the whey-proteids.

After experimenting with different degrees and duration of heat we found that the most convenient method of destroying the rennet in whey was by heating it rapidly to 65° C. We also found that when clear fresh whey was gradually heated, the first slight milkiness in the fluid indicating a precipitation of whey-proteids did not occur until a temperature of 70° C. was reached, and that no considerable coagulation took place till the fluid was heated to over 80° C. The temperature recommended by Westcott, 76.5° C., is too high. The rennet is destroyed at a temperature of 5° C. lower, so that the higher temperature is unnecessary and has the objection of coagulating some of the whey-proteids. This coagulation temperature was not affected by changing

¹ *Allgemeine med. Cent. Zeitung*, 1896, vol. 65, pp. 861-873.

² *Textbook of Physiological Chemistry*, 1900, p. 227.

the reaction of the whey from slightly acid to slightly alkaline by the addition of lime-water.

It is therefore evident that by heating the whey to 65° C. before mixing it with the cream for infant feeding, we accomplish the desired object of destroying the rennet, and preventing the coagulation of the cream, without precipitating the whey-proteids.

Analysis of Whey.—Various analyses were made by Kjeldahl's method to determine the amount of soluble proteid in the original whey. Specimens of whey were also heated to different temperatures, 65°, 68°, 75° and 80° C., filtered, and then analyzed to find out how much proteid had been coagulated at these temperatures.

It was also noted that in unheated whey which stood for 24 hours there usually appeared a very slight flocculent precipitate, but it was shown by analysis that this precipitation did not affect the amount of proteid in the whey appreciably. Analysis of six specimens of whey give the following percent of proteid: 0.99, 1.08, 1.03, 1.01, 1.00, 1.01, the average being 1.02%.

The following figures show the amount of proteid left in a specimen of whey after heating it to the given temperatures and filtering:

Unheated whey	1.08%
Heated to 65° C. and filtered.....	1.04
" " 68° C. " " 	0.98
" " 75° C. " " 	0.97
" " 80° C. " " 	0.95

We see that heating the whey within the limits given, produced only a very slight and gradual coagulation of the proteid. The analyses of our specimens of unheated whey agree with those given by the United States Department of Agriculture in the amount of proteid present, practically 1%, this being somewhat higher than the amount found by Koenig, which is 0.86%.

Westcott has based his formula for cream and whey mixtures on Koenig's analysis of 0.86% proteid in whey; this is probably too low an estimate for American milk, as show by the analysis of the United States Department of Agriculture and by our own, and therefore the amount of total proteid obtained by mixing cream and whey, according to Westcott's formula, is probably actually higher than given in his tables.

Analysis of Whole Milk.—Several analyses by Kjeldahl's method were made to estimate the relative proportion of caseinogen and whey proteid in whole milk, in order to determine this relative proportion in the cream used in the whey-cream mixtures. The average amount of total proteid in whole milk was 3.84%; the average amount of whey-proteids was 0.90%, or approximately $\frac{1}{4}$ of the total proteids; the average amount of caseinogen was 2.94%, or approximately $\frac{3}{4}$ of the total proteids.

COMBINATIONS POSSIBLE IN WHEY-CREAM MODIFICATIONS.

By the use of 32% cream, fat-free milk, and a very concentrated solution of milk-sugar it was found possible on the basis of our analysis of whole milk and whey to obtain whey-cream mixtures with a maximum of 0.90% of whey-proteids in combination with percentages of caseinogen varying from 0.25% to 1.00%, giving total proteids of from 1.15% to 1.90%. A 32% cream must be used in order to obtain the highest percentages of fat with the lowest percentages of caseinogen. A limited number of combinations can be obtained with creams containing less fat, as shown by Westcott.

The precise prescriptions of fat, whey-proteids, caseinogen and sugar which are now possible are given in the following table, the entire credit of which belongs to Mr. J. H. Waterhouse, who made the mathematical calculations for us and has introduced the process into the

Boston milk-laboratory. The extension of the system to the other laboratories of the Walker-Gordon company throughout the country will shortly be accomplished.

Any per cent. of sugar from 4 to 7 may be obtained with any of the above combinations.

EMULSIONS.

Our experimental studies were first directed to a determination of the emulsion of whey-cream mixtures in comparison with other modifications of milk, in test-tubes and in a dog with an artificial gastric fistula.

We compared the emulsion of whey-cream mixtures with that of plain cow's milk, and with ordinary modified milk made in one case from 16% gravity cream, in another from 16% centrifugal cream. Each mixture contained 3.50% of fat, 6.00% of sugar, and 1.00% of total proteids; the latter in the whey mixture consisted of 0.25% of caseinogen and 0.75% of whey proteids. In one series, 5% of lime-water was added to each mixture and one portion heated to 75° C. and another portion was not heated. In a second series the mixtures were put up without lime-water, and one portion was heated to 75° C. and another was not heated.

The tubes prepared in this manner were delivered to us at once, and after being warmed and gently mixed, were examined with a magnification of 625 diameters. The emulsions in all the specimens were uniform and practically could not be distinguished one from another. A repetition of the experiment confirmed our observations. We therefore concluded that whey mixtures, plain milk, gravity cream mixtures, and centrifugal cream mixtures were essentially the same in their emulsion, and that neither the presence nor absence of lime-water, the application or non application of heat for pasteurization, had any influence upon the emulsion.

We repeated the experiments, using the same mixtures, but subjecting them to the influence of transportation. The milk was carted about the city for eight hours and then examined. No disturbance in the emulsion was

noticed either in the gross appearance or microscopically. The unopened bottles after standing 36 hours in the room-temperature were perfectly sweet.

We had, however, noticed, as many others have done, that under certain conditions large, highly-refracting globules in the form of a scum were sometimes seen floating upon the surface of the milk put up at the laboratory. These we analyzed and found to consist principally of fat, indicating that the emulsion had been disturbed. Townsend³ and others have maintained that the use of centrifugal cream combined with transportation was the cause of this disturbance. It is clear from the above experiment that this explanation cannot be accepted.

The experiment was again repeated and the milk examined with the same result. The bottles were then allowed to stand in a comparatively warm place in a kitchen. Twenty-four hours later only the unheated bottles had soured, the remainder were sweet and none of them showed the scum of the separated fat-globules. We concluded from these facts that transportation alone was not sufficient to disturb the emulsion.

Finally we tried the influence of heat and transportation combined. The same series of milk was used again. The tubes were placed in a box, the central compartment of which was kept filled with hot water, and were carted about the city for eight hours. At the end of that time each specimen showed the scum of fat-globules. A second attempt failed to produce this disturbance, but on investigation we found that the hot-water tank had been filled but once and that owing to the cold weather which prevailed the temperature within the box had not been maintained. A third attempt confirmed our first results, and we therefore concluded that it is the combination of heat and transportation which produces the change in the emulsion irrespective of the character of the modified milk. It is also evident from our failure in the second attempt that considerable and prolonged heat is necessary, a condition which prevails only in the hot days of summer. It is in such weather, moreover, that we have most frequently observed the presence of the fat on the surface of the milk. This disturbance of the emulsion can easily be avoided by keeping the milk cool during transportation in hot weather.

To determine whether any difference could be found in the emulsion of gravity cream mixtures and centrifugal cream mixtures during actual gastric digestion we used two mixtures of 3.50% fat, 6.00% sugar and 1.00% proteids; one of these was made from gravity cream and one from centrifugal cream. Each contained 5% of lime-water and was heated to 69°C. The milks were fed to the dog at different times and withdrawn by means of the fistula at the end of 10 minutes. The gastric contents were examined and no essential difference in emulsion was found.

COAGULABILITY.

1. *Experiments in Test-Tubes.*—The character of the coagulum yielded by whey-mixtures in comparison with various cream-mixtures, and barley-water mixtures, was determined in test-tubes, and the results controlled by animal experiments.

The mixtures contained for the most part, 3.50% of fat, 6.00% of milk sugar, 1.00% of proteid.

In order to determine whether the character of the coagulum was influenced by the kind of cream used in

making the mixture, or by the degree of alkalinity, or by the heat used in pasteurizing, some of the mixtures were made up with centrifugal cream, and others with gravity cream, some with 5% of lime-water, others with no lime-water, some specimens were pasteurized at 75°C. while others remained unheated.

The ordinary 3.50—6.00—1.00 mixtures were made up in the following proportions, for 20 ounces:

16% gravity or centrifugal cream	4½ ounces.
Skimmed milk.....	1 ounce.
Water.....	14½ ounces.
Milk sugar.....	1 ounce.

The 3.50—6.00—1.00 whey-mixtures in which 0.75% of the proteid was whey proteid, and 0.25% was caseinogen were made in the following proportions for 20 ounces:

32% cream.....	2½ ounces.
Lime-water	1 ounce.
Whey	16½ ounces.
Milk sugar (dry)	1 ounce.

The barley-water mixtures were made by replacing 10 ounces of the water in 20 ounces of ordinary 3.50—6.00—1.00 mixtures with barley water, making the amount of starch in the milk-mixture about 0.7%. The experiments of White⁴ have shown that this is the best amount of starch to use, when action upon the casein coagulum is desired.

Whole milk was occasionally used for comparison with the milk mixtures, but the essential point was the comparison of plain, centrifugal and gravity cream mixtures, with whey mixtures and barley-water mixtures, with respect to the casein coagulum.

In the experiments in test-tubes the conditions present in the normal stomach were simulated as far as possible. The milk was kept at body temperature and was gently agitated during coagulation by slowly inverting the tubes several times. As the precipitation of casein by dilute acids is a different process from its coagulation by rennet, we tried the action of (a) HCl alone, (b) rennet alone, (c) HCl and rennet combined. The HCl and rennet combined gave rather uncertain results, and it was thought best to judge of this action by animal experiments. Twenty-five ccm. of milk were precipitated by the addition of 0.5 ccm. of 5% HCl, giving 0.1% free HCl in the mixture, which is the normal amount in the healthy adult stomach; in the second case 25 ccm. of milk was coagulated by the addition of 2 ccm. of a liquid rennet preparation. The coagulation was usually prompt and complete within a minute. The size and consistency of the curds were noted and later the tubes were moderately shaken to see whether the curd was tough and tenacious, or soft and easily broken up into small fragments.

The following series of milk mixtures were coagulated by rennet and by HCl separately on 6 occasions with constant results:

No lime water.....	unheated.

There were certain differences in the coagulation of the milk-mixtures which seemed to us unimportant because they were either very slight in degree, or dependent upon the artificial conditions of the test-tube experiments, but they may be briefly mentioned. The curds produced by HCl alone were always somewhat finer than those yielded by rennet. This observation probably has no practical value, as the coagulation of milk in the stomach ordinarily results from the combined action of HCl and rennet. It was also found that when the reaction of the milk was slightly alkaline, from the presence of lime-water, the coagulation by rennet was somewhat delayed and incomplete. This is due to the fact that the action of rennet is inhibited by even a very slight excess of alkali, and has no practical bearing on the coagulation of such a milk-mixture in the stomach, where the alkali would be promptly neutralized.

With reference to the effect of pasteurizing the milk at 75° C., it was found that in about one-half the specimens there was no difference in the coagulum in the heated and the unheated milk; in the rest the difference, although always in favor of the heated milk, was too slight to have any importance.

A comparison of the milk-mixtures brought out the following important facts: The coagulum in whole milk was coarse and tough. The coagulum in the ordinary 3.50—6.00—1.00 mixtures was finer, softer and more flocculent than in the whole milk, which was to be expected since the proteid was reduced from 3.8% to 1% by dilution.

The coagulum was just alike in the mixtures made with gravity and with centrifugal cream.

The coagulum with rennet in the barley-water mixtures was much finer than in the plain mixtures, showing the effect of barley water as a diluent in mechanically separating the particles of coagulum. The coagulation of the barley water and the whey mixtures with HCl was unsatisfactory, owing to the tendency of the fine curd partly to redissolve in a small excess of the acid.

The coagulum with rennet in the whey-mixtures was finest of all, being finer even than that yielded by the barley-water mixtures.

A few specimens of whey-mixtures containing 2% of fat, 5% of sugar, 0.75% of whey-proteids and 0.25% of caseinogen and others containing 3.50% of fat, 6.00% sugar, 0.75% of whey-proteids and 0.50% of caseinogen were compared with the whey-mixture containing 3.50% of fat, 6.00% of sugar, 0.75% of whey-proteids and 0.25% caseinogen and it was found that these variations in the percent of fat, sugar and caseinogen did not affect the fineness of the curd.

To determine whether the amount of fat present had an influence on the tenacity of the casein coagulum, the

following experiment was tried. Specimens of 16% cream were diluted with 2 parts of water, and specimens of fat-free milk, equally diluted were coagulated with rennet. We found that this variation in the amount of fat was without influence, as there was no appreciable difference in the tenacity of the coagulum.

We also wished to determine whether whey, like barley water used as a diluent for casein, had the power of making the coagulum fine and soft by getting between the particles during coagulation and preventing their uniting together into a tough mass.

The following mixtures were coagulated by rennet and the character of the coagulum noted:

1. 16% cream, 1 part; water 2 parts.
2. " " whey 2 parts.
3. " " barley water 2 parts.

The coagulum was coarse in No. 1; finer in No. 2, and much finer in No. 3. It is therefore evident that whey has distinct value as a diluent in making the casein coagulum finer, but in this respect is inferior to barley water.

2. *Animal Experiments.*—We selected from our experiments in test-tubes those results which seemed to us to have the most practical bearing on the coagulation and digestion of milk, and endeavored next to verify them by experiments in the animal stomach. We compared the size and digestibility of the casein coagulum yielded by the following mixtures, all of which contained 3.50% fat, 6.00% milk sugar, and 1.00% proteid, and which were made as follows:

1. Ordinary modified milk made with gravity cream.
2. Ordinary modified milk made with centrifugal cream.
3. Modified milk made with centrifugal cream, and containing 50% of barley water of a strength which gave 0.7% of starch in the mixture.
4. Whey-cream mixture containing 0.75% whey-proteid and 0.25% caseinogen.

Five percent of lime water was added to all the mixtures, and they were pasteurized at 67° C. We also repeated the experiment to determine the value of whey as a diluent.

A dog with a gastric fistula was chosen for this work. We wish to acknowledge our great indebtedness to Dr. M. Vejux-Tyrode, of Boston, who performed a successful operation for fistula upon the dog which we used. The fistula did not leak, the dog remained in healthy condition and even gained in weight during the course of the experiments.

The dog was fed with the milk mixtures, and after a certain interval the gastric contents were allowed to run out by removing the stopper of the fistula tube and the stomach gently irrigated with warm water. Twenty to thirty minutes were allowed to elapse between consecutive experiments. In each case, we noted the amount of the stomach-contents, the character and size of the coagulum, the amount of free HCl present and the total acidity. The object of the chemical examination was to make sure that the stomach was in the same condition in the various experiments.

In Series I the dog was fed with 200 ccm. of ordinary modified milk made with (a) gravity cream, (b) centrifugal cream, and the gastric contents withdrawn in $\frac{1}{2}$ hour.

In Series II the dog received 150 ccm. of (a) ordinary modified milk, (b) modified milk with barley water, (c) whey-cream mixture. The gastric contents were withdrawn in $\frac{1}{2}$ hour.

Series III was a repetition of Series II, using 100 ccm. of the mixtures and withdrawing the gastric contents after 10 minutes.

In Series IV the dog received 100 ccm. of a mixture of 1 part 16% cream with 2 parts of (a) water, (b) whey, (c) barley water. The gastric contents were withdrawn in 10 minutes.

In each series the amount of gastric contents was practically constant, and the acidity varied less than 0.05%; therefore, the differences found in the curds cannot be explained by variations in the condition of the stomach.

It was found that ordinary modified milk made with gravity cream and with centrifugal cream yielded a flocculent coagulum of the same size and character.

Modified milk with barley water and whey-cream mixtures both yielded a much finer and more digestible coagulum than ordinary modified milk.

Modified milk with barley water yielded a coagulum equally as fine as whey-cream mixtures. In one experiment the coagulum in the whey-cream mixture, though equally fine and soft, was less in bulk than the coagulum in the barley-water mixture. This is naturally explained by the smaller amount of caseinogen in the former.

Series IV gave the same result as the corresponding experiment in test-tubes and showed that whey has a distinct value as a diluent in making the casein coagulum finer, but is inferior in this respect to barley water.

In short, the results obtained in test-tubes were confirmed by the animal experiments with the sole exception that in the animal stomach the modified milk with barley water yielded a coagulum just as fine and digestible as the whey-cream mixtures.

CONCLUSIONS.

We may briefly summarize our results as follows:

1. By the use of whey as a diluent of creams of various strengths, we are able to modify cow's milk so that its proportions of caseinogen and whey-proteids will closely correspond to the proportions present in human milk. We therefore render it much more digestible and suitable for infant feeding.
2. The best temperature for destroying the rennet enzyme in whey is 65.5° C. Whey or whey-mixtures should not be heated above 69.3° C. in order to avoid the coagulation of the whey-proteids. The percentage of whey-proteids in the whey obtained by us was 1%, while in the analysis of the whole milk, approximately $\frac{3}{4}$ of the total proteid was caseinogen and $\frac{1}{4}$ was whey-proteids.
3. On the basis of these analyses we were able to obtain whey cream-mixtures, with a maximum of 0.90% and a minimum of 0.25% of whey-proteids in combination with percentages of caseinogen varying from 0.25% to 1.00%; of fats, from 1.00% to 4.00%; of milk-sugar, from 4.00% to 7.00%.
4. The emulsion of fat in whey, barley-water, gravity cream, and centrifugal cream mixtures, were the same, both in their macroscopic and microscopic appearances. The combination of heat and transportation, such as sometimes occurs in hot weather, partially destroys the emulsion in all forms of modified milk, but this disturbance can be prevented by the simple precaution of keeping the milk cool during delivery.
5. Whey cream-mixtures yield a much finer, less bulky, and more digestible coagulum than plain, modified mixture with the same total proteids; the coagu-

lum is equalled in fineness only by that of barley-water mixtures. The coagulum yielded by gravity cream-mixture and centrifugal cream-mixtures is the same in character.

PROPER METHODS OF HANDLING MILK FOR INFANT FEEDING.

By GEORGE THOMAS PALMER, M.D.,

of Chicago, Ill.

Medical Director of Trinity Diet Kitchen for Infants; Instructor in Pediatrics at the Chicago Clinical School.

THE practitioner who has labored long in the field of infant feeding cannot but feel a great sense of satisfaction as he sees the subject tending to logical simplicity both of theory and practice. It is gratifying for him to see the unanimity of opinion in regard to cow's milk for infant feeding; to realize that the minute percentages in milk modification which have been so troublesome in the past, are not absolutely essential; to see the rapid growth of the sentiment against sterilization and pasteurization and to be able to feed with safety a raw milk as the result of the intelligent study of dairymen.

There is hardly a practitioner today who will dispute the preeminent advantages of cow's milk over any other form of substitute feeding; and the opinion has been logically formulated that sterilization, being injurious to the milk, is at best a necessary evil, and an evil which is not necessary if proper dairy methods are carried out. As to minute modification, Jacobi was certainly practical and logical when he called the attention of physicians to the marked variations in the milk of the healthful mother, not only from day to day; but from morning to evening; and remarked that if the slight alterations and changes in the percentages of modified milk were as dangerous as they are made out to be, there would not be one living child in all Creation. He and many other writers have called the attention of pediatricians to the fact that clean milk is far more important than any amount of modification.

That clean milk can be procured in all the large cities is absolutely certain. I do not say that sterile milk can be found, for it is known that the milk is invaded with certain forms of bacteria before leaving the udder of the healthy cow; but milk that is free from the bacterial life deleterious to the infant can certainly be obtained. That such a milk is better than cooked milk is beyond question. It is conceded that cooking makes the food less easily digestible and decreases the nutritive value, and it is further known that even if we sterilize we must have a relatively pure milk, for no amount of sterilization can purify a milk already foul, and impregnated with the products of bacterial growth.

When it is known that sterilized milk is more or less injurious; when it is known that pure milk can be secured by proper attention to the dairy, certainly the basis of infant feeding is established. That basis is raw milk.

It is not my desire, however, to enter into any discussion of sterilization or pasteurization; but merely to speak briefly of the methods that can be and are employed to produce a milk fit for infant feeding in its raw state.

Trinity Diet Kitchen for Infants, a milk charity in the poor district of Chicago, was opened with the idea of supplying a pure, modified cow's milk to be distributed without any attempt at sterilization. During

the summer just past we have carried out this plan, and although the infant mortality in the city has been very high and the weather intensely hot (one month of the hottest weather ever recorded by the Weather Bureau), we have had a mortality of something less than 1%. We have never given out 1 ounce of either sterilized or pasteurized milk, and we have been so gratified with our results that we have had no disposition to do so. It may be further stated that we have had almost no complaints of the milk souring, although our clientele has been the poor and their hygienic surroundings exceedingly bad. We have merely taken the precaution to have everything coming in contact with the milk perfectly sterile and of packing each supply with a liberal quantity of ice before permitting it to go out. The amount of ice given for each child has been ample to keep the food cold and sweet for the greater part of the day and instructions are invariably given that the ice be replenished when it runs low.

Our success in feeding with raw milk in unsanitary surroundings, I believe to be due, first, to the unvarying purity of the milk; second, to the care given the milk in our kitchen. The rigid instructions given the parents in regard to handling the milk, regularity of feeding, and absolute cleanliness has also been a factor; and this instruction is the more effective on account of the repeated calls made by our superintendent and nurses to see that our instructions are being carried out to the letter.

Through the courtesy of Mr. H. B. Gurler, of DeKalb, Illinois, I was able to closely inspect the methods of his farm from which our milk is derived.

The cattle I found to be good, healthy stock, all tuberculin-tested by the authorities of the State. They were originally Holstein, Jersey, Durham, and Guernsey stock; but for several years they have been invariably bred to Holstein bulls, so that at present the herd is almost altogether Holstein. The preference for Holsteins is accounted for by their ruggedness and almost invariably good health, as well as for the evenly balanced milk they give. The tendency on the part of dairymen, however, to force the Holsteins to the very largest amount of milk they could give, has caused a deterioration in the richness of the milk, and this Mr. Gurler has overcome by breeding with a view to increasing the butter fats. The cows now on the farm do not give the quantity of milk they formerly did; but the butter fats have increased so markedly that the milk is almost a rival of the Jersey.

The tuberculin test proved only 3% of this herd to be tuberculous, while the average percentage in the herds of this part of the country is from 12 to 14%. No full grown cow actually born and raised on this farm has responded to the tuberculin test, on account of the ideal hygienic conditions. A sick cow afflicted with any malady whatever is at once isolated and not permitted to come in any way in contact with the herd. The barns used by these sick cattle are never occupied by the healthy stock. The herd is never permitted to drink from ponds or streams, and the only water they get is pumped into perfectly clean troughs from an artesian well. The food is perfectly clean and the cattle are curried and groomed regularly. The udders are kept in good condition by washing, which occurs twice daily, and there is a comparative freedom from infective processes of the udder on account of the fact that the cattle are not overfed or forced to give their greatest possible quantity of milk. Stockmen have found that overfeed-

ing is a common source of disturbances in the udder. Any cow with infected udder is at once isolated.

Another reason for the comparative freedom from tuberculosis is that the calves are fed only upon the milk of perfectly healthy tuberculin-tested cows and not upon the skimmed milk of unknown herds, secured from creameries, as is generally done in this region.

The food most depended upon is chopped cornstalks gathered when the corn is fully developed and when the kernels have dented, but cut and stored in silos before it has been permitted to dry. That this is a satisfactory food is indicated from the fact that when other foods are used in its place the milk decreases in both quantity and quality. In addition to this, silage, bran, shorts, and gluten meal are given, and during summer there is most excellent pasturage. In turning the cows into pasture, however, the greatest care is exercised, for the new grass almost invariably causes diarrhea in the cow. Even if green-grass feeding is not permitted to this extent, Mr. Gurler has raised the question as to whether the green feeding could not cause diarrhea in the child using the milk, even though the cow were not affected. He tells, in support of his theory, that when laxative foods are given to a sow with a fresh litter, the sucking pigs are often badly "scalded" when no tendency to diarrhea is noticed in the dam.

The milking is done at three in the morning and three in the afternoon, in stables with cement floors so slanted as to permit thorough scrubbing, which is done daily. The milkers are clothed in white, clean suits, and use buckets which are covered with a cap holding in place two thicknesses of sterilized gauze between which is placed a thick layer of absorbent cotton. The milk passes through this gauze and cotton before reaching the pail.

The udder washers precede the milkers and thoroughly cleanse the udders. The milker then draws a considerable amount of milk from each quarter and puts it in a pail for disposal. He then milks through the strainer and when his bucket is full, empties the milk into a sterile can, in which process it is again strained. These cans are taken up and reach the dairy within 5 minutes after milking. The milk is poured at once into the receiver of the separator and in about 10 seconds passes through and is run into buckets. The milk and cream are mixed again at once, except that excess of cream or milk which must be taken out to maintain the standard of 4% guaranteed. From the separator the milk is poured at once into the receiver of the cooler, from which it trickles down over coils of pipe filled with ice water and at the bottom falls into other pails, having in the process attained a temperature of about 45° F. This temperature is reached in about 10 or 12 minutes after milking. Within 20 minutes the bottles are filled and sealed, ready for shipping. They are sent into the city in sealed cases packed in shaved ice.

The precautions in regard to cleanliness of this institution would do credit to a hospital. Every article used in the place stands for hours in a large steam sterilizing room before use.

The process of separation as here carried on, not only permits a uniform quality of milk, but removes from the milk the mucus and slime and occasional blood-clots found in all milk. It is stated also that the number of bacteria is considerably decreased.

It is this care and attention to the dairy which places infant-feeding upon a natural and sound basis, and this is the care which makes preservatives and sterilization

equally unnecessary. On the day on which I visited the farm, several cases of this milk were shipped to Paris, with every confidence that it would reach the European city in perfect condition. Certain it is that this milk has been kept on ice in Trinity Diet Kitchen for Infants for almost two weeks with no sign of souring or decomposition.

I am aware that able men advocate sterilization, especially when feeding under circumstances where the environment is not satisfactory; but I am firmly convinced that he who teaches sterilization teaches a bridging over of faults which should not have been committed; advocates an injurious food for an infant when a little care and brain would have made it unnecessary. To teach sterilization is like teaching the medical student the use of antidotes for overdose of drugs without teaching him anything of proper dosage or how the overdose may be avoided.

After trying a raw milk with the infants of the poor during a terribly hot season, and having seen what can be done toward the preparation of a clean, pure milk, I am ready to banish forever sterilization or pasteurization on the same ground that I would banish formaldehyd or any milk preservative—on the ground that they are both injurious and unnecessary.

THE IMPORTANCE OF INSTRUCTION IN MEDICAL SCHOOLS ON THE MODIFICATION OF MILK FOR PRESCRIPTION FEEDING.

By ANDREW H. WHITRIDGE, M.D.,

of Baltimore, Md.

DURING the course of instruction, in any modern medical school, students have opportunity to study more or less practically the relation of bacteriology to pathology. Students, in the second and third years of the course, gain enough laboratory experience of the more important species of bacteria to enable them to make a diagnosis of infected tissue given for examination. As students approach matriculation a very distinct and imperative impression has been created of the role played by bacteria, both in health and disease, and of the methods employed to deal with those that are regarded as pathogenic in their action. Asepsis and antisepsis are familiar both in theory and in practice, not only in relation to surgery, but also in the proper estimation of the etiology and treatment of disease, whether regarded as strictly communicable or not.

The progress of bacteriology has been very rapid, starting indeed in the realm of surgery, where it has seized the operative field as its own; yet scarcely less dominant in the domain of medicine, and perhaps most authoritative in the comparatively unobtrusive region of preventive medicine. All this rapid accumulation of ascertained facts, and the brilliant application of them to practice, deeply impress the mind of the graduating student, and equip him with a zeal according to knowledge, unknown to his professional brethren of an olden time. The young practitioner feels that he starts out with a large measure of wisdom, which is knowledge put to use; especially when he is called upon to combat those diseases in which his academic study of bacteriology and his practical work in the laboratory of the medical school afford him both a correct diagnosis and an adequate treatment. He feels somewhat at home, even in the company of older men,

when he has to deal with the problems to which bacteriology holds the key.

But it is far otherwise when he is called upon to decide many of the common questions and to dictate daily procedures of general practice. The art of preventive medicine, as applied to the life of the family, is often a puzzling and unsatisfactory practice. Yet it ought to be one of the chief sources of satisfaction in medical practice. The intelligent laity is calling for the advice and cooperation of the profession in thousands of ways outside of treatment for actual sickness or injury. The care of the body in health is as paramount a consideration with intelligent patients as is its cure in time of sickness.

Questions of sanitation, the practical hygiene of the kitchen, bed- and bath-rooms, and especially of the nursery, dietaries for the man of active business, or of sedentary habits, for the school children, for the aged, and especially for the mother and her baby, are now questions for solution by the family physician, and may soon be problems for specialists in this department. These great matters should form an important part of the curriculum of the modern medical school, yet they do not. Those physicians who are now eminent for their work in preventive medicine and hygiene are those who have studied these subjects since graduation, and, with some exceptions, for whom their medical school education did very little to equip them to follow a natural bent in these directions. Let this question be illustrated by one example taken from the many that might be cited, viz, the most important and pressing question of infant feeding.

During the past 15 years we have witnessed a great change pass over this question, both in the minds of the laity and in those of the members of our profession. We have seen a few aspects of this question change from hazy uncertainty into a phase of enlightenment. This change has always been as remarkable as it is encouraging to the profession. For example, it is conceded that the feeding of infants should be wholly under the control of the physician. Just as the midwife has been superseded by the obstetrician, the ignorant nurse or untrained mother must be superseded by the trained and qualified physician. This position is held by the intelligent layman quite as firmly as it ought to be held by the educated physician. That it is very frequently more firmly maintained by the patient than by the physician is largely due to those medical schools which have neglected to prepare the physician for this important and remunerative work. A large part of the mortality of infancy is traceable to the lack of importance given to the subject of scientific feeding in the schools.

It is also conceded that in the absence of the proper breast milk some modification of animal milk should be employed as a substitute, and that cow's milk should form the basis of all scientific infant feeding. From this position there is now no deviation. Specialists differ as to the forms of modification, as to percentages and proportions, as to diluents, and other matters of detail. But none differ from the general proposition stated above. But scientific substitute feeding requires an intimate knowledge of milk; of breast milk as the primary example, and of modified cow's milk as the practical copy. It is not the fault of the average physician that this subject is to him very often a *terra incognita*. It is mostly the failure of the medical school to lay the suitable foundation for the experimental knowledge.

It is conceded that the modification of milk for infant feeding is a very simple thing of itself. Yet it is often regarded as a mystery and a scare, in medical practice. The schools might make its complete study one of the simplest as well as one of the surest means of practical education.

In our medical schools of the South there are no means by which the student or the postgraduate physician can obtain the training necessary to enable him to conduct thoroughly scientific infant or invalid feeding. Students in some of our Northern schools of medicine have opportunities to become more or less familiar with this branch of medicine, but in the South they have no such opportunities. These should be supplied; and I here make an earnest appeal that medical schools in the South obtain qualified men, even if they be not all doctors, who will devote their time and energy to the teaching of this great subject.

Since summer diarrhea is such a factor in our mortality, I suggest that, at least during the summer months, such of our schools as maintain a high standard of education should appoint qualified men who shall instruct, by regular weekly lectures, students and postgraduate physicians in the practical knowledge needed to understand this branch of our work. It would be an inestimable gain to earnest men to have such knowledge of the cow, her milk, its care, and the bacteriological relation of such matters to the employment of milk for infant feeding, imparted by a competent instructor. If such a chair were founded, in our school, for example, and a proper man found to fill it, we should realize that advance had been made in pediatrics.

The milk laboratories that have been established in many cities of the United States have done much to further the scientific feeding of infants. Those physicians who employ these laboratories most largely speak most strongly of the results obtained. My own experience in the use of milk, modified according to my prescriptions, at the laboratories, has been so satisfactory that I cannot praise this method too highly, and I should like to see a milk laboratory within the reach of all physicians who have infants to feed artificially. This, however, is impossible, and at best only a percentage of physicians can reach the laboratories with their prescriptions. But all physicians intending to devote themselves either to general medicine or to the special work of pediatrics should be permitted and encouraged to lay a solid foundation for this work while they are in the medical school. Therefore, I hope my appeal for special instruction in feeding will not be made in vain.

INTRACRANIAL HEMORRHAGE IN THE NEWBORN.

By W. REYNOLDS WILSON, M.D.,

of Philadelphia.

INTRACRANIAL hemorrhage in the newborn is usually the result of rhexis affecting the vessels of the meninges. It is a natural consequence of the traumatism of birth. Meningeal apoplexy, according to Cruveilhier, may be considered as the cause of death in one-third of the infants who succumb sub-partu or shortly after birth. In the experience of the writer 15 instances of intracranial hemorrhage were noted in 20 autopsies performed upon the bodies of infants dead within 3 weeks of birth. Cerebral congestion without meningeal

hemorrhage is rarely noted portmortem on account, first, of the frequency of traumatic influence in determining hemorrhage, and second, on account of the frailness of the vessel walls subjected to the pressure of augmented vascular tension.

The character of the labor as well as the presentation and position of the child are to be considered in their bearing upon the etiology of meningeal hemorrhage. Traumatic deliveries, considered in the sense of operative deliveries (instrumental or otherwise), however, are not solely responsible for intracranial hemorrhage. Natural or spontaneous deliveries, where the fetus is subjected to long-continued pressure, contribute a quota of the deaths due to this lesion in the newborn.

The classification of these hemorrhages may be: (1) Anatomical, that is, as to the location of the effusion occupying the meningeal spaces; (2) etiological, as to the occurrence of the hemorrhage primarily from traumatism, or secondarily from mechanical causes, such as pressure acting either upon the vessels within the cranium or interfering with the intracranial circulation from without. Cachectic conditions dependent upon vicious development or nutritional defects are to be included as causes.

The anatomical classification of intracranial hemorrhage serves, perhaps, the better purpose of description. It may be arranged as follows:

(1) Extrameningeal; (2) arachnoid, or subdural; (3) subarachnoid; (4) ventricular; (5) mixed.

Cerebral apoplexy proper is of rare occurrence in the newborn.

EXTRAMENINGEAL.

The dura mater is closely applied by its outer or periosteal lamina to the interior of the skull. This adherence is especially intimate in the newborn. Extrameningeal hemorrhage (cephalhematoma interna) is therefore rare. Traumatism sufficient to cause laceration of the middle meningeal artery or its branches are usually the cause of effusion in this region. Fracture of the flat bones during birth generally involves extensive laceration of the extradural vessels. The longitudinal sinus is rarely the source of bleeding. Extrameningeal hemorrhage is usually accompanied by invasion of the arachnoid cavity. This form of hemorrhage, if extensive, reveals itself directly by marked symptoms. The immediate results may give rise to grave symptoms of impaired motility and sensibility.

It is not impossible for absorption to take place. The fluid portion of the blood may first be absorbed, the remainder of the effusion existing as a blood cyst.

ARACHNOID OR SUBDURAL.

Arachnoid hemorrhage is the result of effusion into the cavity limited by the arachnoid membrane beneath and the inner or supporting lamina of the dura.

The origin of this form of hemorrhage is usually traumatic. The liability to rupture of the arteries and veins traversing the surface of the convolutions is easily comprehended when the character of the membranes supporting these vessels is considered. The pia, for instance, is nothing more than a network of delicate vessels which are held together by the supporting areolar tissue. The subarachnoid tissue also, which bridges over the space between the pia and the dural surface of the arachnoid, consists of fine trabeculae in

no way constituted to withstand the shock of traumatism. In addition to this the cortical veins have extremely thin walls. They are without muscular coat and are unfurnished with valves (Morris, *Text-Book of Anatomy*). The traumatic conditions, therefore, existing during birth are favorable to rupture of these cortical vessels irrespective of traumatism. Pressure due to obstruction of mechanical origin during birth or to pathological conditions in extrauterine life may so increase venous pressure as to cause rupture with extravasation.

The causes, therefore, of subdural hemorrhage, according to Barthez and Sanné, may be summarized as follows:

1. Direct injury to the vessels from compression of the head during its expulsion.
2. Unusual molding of the head.
3. Torsion of the cervical vertebrae during forcible extraction of the head.
4. Constriction and winding of the cord.
5. Compression of the thorax incidental to protracted labor.

Among the causes operative alike sub partu and after birth it is necessary to consider also arrest in the encephalic circulation from intra or extracranial pressure. Obstruction of such character may be due to:

1. Neoplastic growths within the cranium.
2. Compression of the superior vena cava by bronchial nodes.
2. Compression of the abdominal vessels by tumors of the liver, spleen and mesenteric glands.

The cachexiae of the newborn—syphilis, tuberculosis, purpuric conditions, and malnutrition, especially in premature infants—may predispose to intracranial hemorrhage.

The compression hemorrhages are likely to be of gradual occurrence and are sometimes unaccompanied by important symptoms. They may, therefore, be overlooked as a cause of death in the newborn. Serous infiltration of the subarachnoid space together with hydrocephalus is apt to occur coincidentally with hemorrhage. On the other hand, in athrepsia the cerebrospinal fluid is lessened. In this way the natural protection to the encephalic vessels is lessened (Parrot). As to the pathological evidences, the subdural space may be occupied by an effusion representing a more or less extensive hemorrhage. The extravasation may extend over both hemispheres, but it rarely involves the anterior lobes. The blood is not apt to become completely clotted, although small shred-like clots are sometimes found adherent to the arachnoid and dural surfaces. The effused blood may separate into two layers, one consisting of an imperfectly-formed coagulum bearing the imprint of the convolutions which are sometimes swollen and flattened, the other composed of a granular deposit adherent to the dura. In other instances the solid portion of the blood becomes absorbed while the liquid remains, giving rise to external hydrocephalus. According to Parrot it is even possible for the effused blood to become completely absorbed.

The extravasation may vary in extent from a few grams to 100 grams or more.

The points of rhexis are rarely to be found. The ventricles are usually not invaded in meningeal hemorrhage, although the choroid plexuses partake of the engorgement, which is evidenced by the general hyperemia of the meninges. Externally the periosteum also

may be the seat of extensive hyperemia even in cases where there is no evidence of external traumatism. The sinuses of the dura and the plexus of veins held within the substance of the dura mater, and constituting the basilar sinus are usually found distended with blackish partially-formed clots. The fibrinous envelope which surrounds physiological coagula is rarely found in instances of subdural effusion. The membranous pellicle consequent to secondary inflammation following hemorrhage is also absent.

SUBARACHNOID.

The locus of the effusion in subarachnoid hemorrhage is the subarachnoid space proper, that is, between the arachnoid and the pia, or between the pia and the brain.

The causes of subarachnoid hemorrhage are the same as those responsible for subdural extravasation; namely, rupture due to traumata or embarrassment of the encephalic circulation. The dyscrasia of purpura and the conditions present in athrepsia may culminate in subarachnoid effusion. Thrombosis of the sinuses of the dura mater and pressure from intracranial aneurysms may be noted as causes of hemorrhage in this locality.

The effusions may be of varying extent and volume, appearing either as disseminated points of extravasation on the surface of the pia or as a thick layer covering the surface of the brain. In extensive extravasation with edema the convolutions may be flattened as the result of pressure. The blood, when freshly effused, is liquid, syrupy and brown in color. It may form solid blackish coagula that recall the fleshy clots of the heart cavities. The clot is usually firmly applied to the convolutions and forced into the intervening depressions. It is usually detachable, but in some instances may be so adherent as to drag away portions of the brain in its removal. The localized effusion never ultimately becomes encysted. (Barthez and Sanné.)

The effusion commonly occupies the convexities of the cerebral hemispheres and the surface of the cerebellum. It may involve the base of the brain, penetrating to the spinal canal and to the ventricles by means of the foramen of Majendie. The effusion may be limited to one side of the brain-surface. The veins of the pia, on account of their voluminousness, usually exhibit extensive engorgement, being distended with blackish coagula. The sinuses of the dura are also distended with clots. When the blood is abundant and the effusion of long standing the convolutions of the brain may be flattened and pressed out of shape. The brain may be the seat of local atrophy (porencephalus).

VENTRICULAR.

Ventricular hemorrhage may occur by the extension of the effusion in the subarachnoid space. Primary hemorrhage is rare, except from rupture of the choroid plexus.

MIXED.

Mixed hemorrhage is characterized by the presence of blood in the subdural and subarachnoid spaces as well as in the ventricles. Such hemorrhage is commonly due to severe trauma.

SYMPTOMS OF INTRACRANIAL HEMORRHAGE.

Should the infant survive the shock of delivery and the

asphyxia which is apt to accompany hemorrhage—the results of difficult labor—the primary symptoms may be masked. At first nothing abnormal may be noticed about the child. This is especially the case if the lesion be of intrauterine origin. If the hemorrhage occur in extrauterine life, the evidences are more or less acute in character.

The symptom-complex is usually as follows: somnolence, anorexia, digestive disturbances with vomiting (the vomited material sometimes consisting of bloody mucus), piercing, hoarse and fretful cry, contraction or dilation of the pupils, convulsions. The outcome of the case is usually fatal, death being preceded by a condition of coma. The temperature is variable and irregular. A continued rise in temperature is not commonly observed. Ordinarily a moderate rise with irregular depressions and exacerbations continues until a few hours previous to death, when a sudden antemortem rise takes place. Exceptionally a depression in temperature occurs coincidentally with the exhaustion preceding death.

The following description of meningeal hemorrhage is typical of the course of such cases: The infant of Mrs. K. was extracted by forceps, after a delay of $3\frac{1}{2}$ hours with the head fixed in the pelvic cavity. The evidences of intrauterine asphyxia were present in the irregularity of the fetal heart-sounds and the presence of meconium in the amniotic fluid. The child nursed and seemed well unto 4 days after birth, when nystagmus of both eyes was noticed. The temperature on morning of the fourth day was 101.2° . On the following day marked opisthotonos was observed. The infant's cry was shrill and incessant.

On the sixth day internal deviation of both eyes was present. The infant was cyanosed and exhibited venous congestion of the surface in the region of the head and thorax. The tongue and lips were red and glazed. The right corner of the mouth was drawn downward and the under lip depressed. The emaciation was very marked, the child having lost $1\frac{3}{4}$ pounds since birth. The arms were extended and rigid, the fingers being flexed, and the thumbs inverted. The evening temperature was 95° F. The respirations were labored, 72 to the minute. General spasmodic movements were present.

On the seventh day the child was unable to swallow. At that time it had not been known to urinate for 2 days. General convulsions occurred, followed by coma and death.

Secondary to the shock, the result of the lesion, the effects of cerebral compression are shown in paralysis with spasm of all the extremities (diplegia). Hemiplegia or paraplegia may occur as a possible consequence of hemorrhage (Rotch). Hyperesthesia is a marked symptom. In certain instances the course of the case may be marked by a condition of total relaxation. In other cases the phenomena of compression and the consequent paralyzes may appear insiduously and therefore escape detection.

DIAGNOSIS OF INTRACRANIAL HEMORRHAGE.

The evidences of a central paralysis are usually indicative of hemorrhage. The condition of the anterior fontanel should be noted; in hemorrhage the intracranial pressure is greatly increased, causing a bulging of the fontanel, whereas in athrepsia or acute conditions accompanied by defective nutrition there is a depression.

Conditions of cerebral congestion may occur secondary to other acute lesions in the newborn, such as asphyxia, lobular pneumonia, disturbances in the gastroenteric tract, septicemia, and tuberculosis. In cases where the hemorrhage occurs as a manifestation of certain cachexia, the association of icterus and the translucent edema of the extremities is to be observed. Ecchymoses in the pleura, the pericardium, the mucosa of the upper intestinal tract, and hemorrhagic infarcts of the lung are commonly met with postmortem as having been associated with the principal hemorrhagic lesion.

PROGNOSIS OF INTRACRANIAL HEMORRHAGE.

Extensive meningeal hemorrhage is not likely to be absorbed. Hemorrhagic conditions occurring sub partu when associated with the milder degree of asphyxia may permit of recovery. Where recovery occurs in such cases the diagnosis is open to doubt, as cerebral congestion may be accountable for the supposed evidences of compression. The latter effects of hemorrhage, resulting in secondary pachymeningitis, may be observed. Permanent contractures, idiocy and sensorial disturbances may be the final outcome. Encephalitis and leptomeningitis are rarely observed as consequences of hemorrhage. Hemorrhagic foci compatible with life may exist and in some instances may be accountable for the origin of external hydrocephalus.

TREATMENT OF INTRACRANIAL HEMORRHAGE.

According to Jewett, the primary object in treatment in hemorrhagic lesions occurring during birth and associated with asphyxia, is to overcome the atelectasis by forced respiration. Schultz's method for the induction of artificial respiration, warm whisky baths, and inflation of the lungs by forced inspiration, should be resorted to. The infant should be regularly immersed in a warm bath (temperature 105°) at intervals of an hour. While in the bath the surface should be gently rubbed. In the intervals between bathing the infant should be enveloped in a light blanket, and the peripheral circulation stimulated by heaters applied to the lower extremities. An ice-cap should be constantly applied to the head. Small doses of sodium bromid ($\frac{1}{2}$ gr.) combined with tincture of digitalis ($\frac{1}{4}$ gt.) may be given at two-hour intervals. Inhalations of oxygen may be used to counteract the results of inactivity of the respiratory center. In case the infant is unable to suckle, human milk may be administered after being pumped from the breast. If breast milk is not obtainable, peptonized milk, one to seven, or a mixture containing two ounces of milk, two of cream, fifteen of sterilized water, one of lime water, milk sugar $3\frac{1}{2}$ drams (F. 1, S. 5, P. 0.75) may be given by means of a medicine dropper. In the writer's experience the administration of whisky is without benefit.

The Demonstration of Bile Pigment in the Urine in Cardiac Affections.—F. Ott (*M. schweizer med. Wochenschrift*, 1900, No. 27). In order to determine the question whether the yellowish discoloration of the skin in grave cardiac affections is due to a true **bilirubin-icterus** or to other pigments, the urine of a series of cases was examined, both by Gmelin's and the improved Salkowski tests. Positive results were obtained in 12 cases. By Salkowski's method bile-pigment is not detected in the urine when the latter contains much albumin or even hemoglobin; neither when medicaments like salol have been taken. [M.R.D.]

THE CAUSES AND TREATMENT OF URGENT AND SERIOUS CONDITIONS IN THE NEWBORN.*

By SAMUEL WOLFE, A.M., M.D.,

of Philadelphia.

Physician to the Samaritan Hospital, Philadelphia.

IF WE leave out of consideration malformations and monstrosities, the causes for such conditions may be divided into: (1) Premature birth; (2) plural births; (3) pressure on the umbilical cord; (4) pressure on the head; (5) pressure on the thorax; (6) toxic conditions of the fetal blood incident to emotional and somatic states incited in the mother during parturition; (7) essential conditions of the fetus.

Premature Birth.—Very few children survive when born prior to the beginning of the seventh month of gestation. The number is, however, materially increased by modern incubator methods of treatment. It is not an easy matter to fix on any organ or function the difficulty or inability of the infant to sustain extrauterine life from the time it is considered viable to the time when in due course of development it is intended for this phase of its existence. The immature condition of the bulbar centers, which preside over the more distinctly vital functions, as well as the unripe state of the organs directly concerned in circulation, respiration and nutrition are all concerned. The work which that large and important organ, the placenta, would in a normal relation have continued to perform for a period of some weeks, must now be done by structures that lack the morphologic and histologic perfection, fully adapted to it. Most practically, if not most scientifically, we may speak of feeble vitality, general immaturity, and inadequate adaptation. Life for the time being, is pathologic, rather than physiologic. Nature's plans have been disturbed, powerful influences are prematurely demanding acceptance or resistance.

Plural Births.—Twin pregnancies present, even at full term, quite often somewhat immature products. Vitality in one or both is apt to be low, and death of one or both is more common than under the same circumstances where the birth is single. The same remarks apply with progressively greater force to plural births where the number exceeds two. If to the element of plurality that of premature nativity is added, the chances for survival are still further lessened.

Pressure on the Umbilical Cord.—Any degree of pressure that interferes with the circulation through the cord must be injurious as affecting not only the respiratory function of the child, but as interfering with the whole train of metabolic functions which are served by it. It is probable that incomplete obliteration of the circulation, while transmitting enough oxygen to sustain life, if long continued, results in some of those conditions which we will consider in subsequent sections, and which are more difficult to deal with than the asphyxia that results from a comparatively short, complete compression. It is well to remember that there passes through the cord to the placenta not only CO₂, but all waste products of metabolism, which in extrauterine life go to such emunctories as the kidneys and skin, while from the placenta the blood carries not only oxygen but nutritive proteids. Bearing all this in mind we may see that in partial interference with the placental circulation degrees of inanition and of toxemia

comparable to uremia may be established. While we may admit that asphyxia is the chief result from compression of the cord, we need not and should not ignore the associated effects. Indeed we are forced to the conclusion that in some cases (the ones, too, most serious to deal with), these usually secondary considerations become primary in importance.

A mechanical effect of pressure on the cord is the clamoring back of the blood on to the central organs of circulation, with consequent distention and final stoppage.

Pressure on the Head.—Pressure on the head must be quite prolonged and very severe to do serious injury in the more ordinary presentations and positions. When exerted in certain directions, it may result in apoplexy and paralysis, or in such injuries as lead to the cerebral birth palsies, which develop beyond the period of infantile life which we are now considering, and will therefore in the present paper be left out.

I can, however, see no good reason for doubting that head-pressure is occasionally concerned in the production of those apparently lifeless infants, by serious interference with the functions of the important centers in the medulla oblongata, which prevent the normal establishment of the respiration, circulation and digestion. An atelectatic lung, a feebly innervated heart, or a failure of the infant to suckle or digest, one or all, may be the expression of such a condition of the nervous centers.

Pressure on the Thorax.—Whether pressure on the thorax can of itself beget any very serious danger to the life of the infant, I admit is rather questionable. In certain positions, and especially in breech presentations when prolonged, I am inclined to believe that it can seriously interfere with the action of the heart, and thus be an element of danger, both before delivery and by a continuation of the effect after birth.

Toxic States of the Fetal Blood Incident to Parturition.—The effect of depressing emotions on the mother's milk, as well as the reactions of psychical states on somatic functions generally, are sufficiently well recognized to warrant the belief that the mother's feelings can have an effect on the vitality of her unborn child. Close observation on the part of the accoucheur will, I think, tend to confirm this view. Prolonged suffering, great nervousness and excitement, anxiety and fear relating to herself and child, especially when coupled with the exhaustion due to the physical strain of labor, and which they materially increase, bode no good for the vitality of the child. When joined to more directly acting causes, with which they are often associated, the gravity of the situation is increased. As to its pathology while obscurity may be still sufficient to allow the skeptic to smile at its mention, there is a fairly rational explanation in a hypothetical toxin. This, transferred through the placental circulation and acting on nervous and muscular structure especially, may be assumed to work very decided mischief. Especially impressionable to such a cause we might suppose the medullary centers, whose normal condition is so important.

Essential Conditions of the Fetus.—Under this head, without limiting myself too severely to scientific accuracy, I have thought it practical to classify such conditions of the child as are inherent in the germ, whether derived from the ovule or the spermatazoa or both. Also such as affect the development of its constitutional characteristics, due to influences acting on it throughout

* Read before the meeting of the Montgomery County Medical Society, at Norristown, Pa., October 10, 1900.

gestation. Improper hygiene and sanitation, acute or chronic diseases, mental suffering or physical abuse acting on the mother during any period of her pregnancy are all more or less influential in determining the health, development, and vitality of the child. The discussion of the transmission of syphilis, tuberculosis, neurosis, and other diatheses, would lead into heredity in all directions, and must be here avoided, but its mention under this heading is fully relevant.

The indications for treatment are of course best evolved out of the most complete knowledge and recognition of the numerous acting causes, together with the pathological conditions they produce, and the means which scientific medicine has revealed that can be applied in removing or overcoming them. Still, too refined a scientific method, here as elsewhere, may rather conduce to hesitation and irresolution than to that prompt and bold action which is best suited to successful procedure and results. A cool head, quick decision, good sense, and prompt action are all necessary.

In formulating indications and suggesting methods I shall not be exactly guided by the text of the etiology or the pathology. As a matter of fact, at the moment of birth the accoucheur may find thrust on his immediate care a fully developed, lusty infant, which even before the whole body is extruded, cries heartily and exhibits every sign of strong vitality and good health. He has but little to do, except to congratulate and compliment the mother, to wait a short time before tying and severing the cord, and then to pass the embryo man or woman, who is expected to mould the destinies of nations, to a smiling and bustling nurse. Or he may have one of two other things—a blue, bloated, breathless baby, or a pale, withered, relaxed, nerveless, pitiable, and apparently lifeless creature.

In the first instance, a slap on the buttocks, a sweep of the finger over the fauces, or a touch to the glottis, will often be rewarded by a good loud cry, and soon the normal color is appearing, and in a short time all is well. Occasionally one may be obliged to give the youngster a good dash of cold water on the face, chest, or back, and to roll it for a moment or two on the bed before one gets so satisfactory a result. But generally, when once there has been a good cry, unless the child is otherwise feeble and immature, anxiety is over, and, to tell the truth, with the experienced doctor has hardly at any time been present.

In the second instance, however, from the first the practitioner may have grave doubts of the outcome. With the cord uncut, he proceeds first, as in the former instances, attempting to start respiration by reflex excitement. Failing in this as he often will, he begins the Sylvester method, changing by and by to the Marshall Hall method of artificial respiration. Or he may make traction intermittently on the tongue, or he may thrust his finger through the anus to dilate rapidly the sphincter, or resort to mouth-to-mouth inflation. Failing still, he calls for two vessels, one with cold and the other with hot water. Dips the child for a considerable period into the hot bath, and then for a moment into the cold, repeating again and again. He has refrained from cutting the cord, but now determines on this and allows a small quantity, a few teaspoonfuls of blood to flow from it. He then may again resort to one or another of the methods already enumerated, or possibly adopt the method of Byrd or of Schultze. Somewhere along the line he may have seen a quick spasmodic gasp, or have heard a feeble moan, and he is encouraged to work on,

now and then after many minutes, or even an hour or more of strenuous work, to succeed fairly in establishing a rather feeble respiration. But he is not yet done with his charge, as we shall presently see. We have been traveling fast in the last few minutes, and lest you may charge me with haphazard, reckless and excited procedure, I must make myself a little more clear. I by no means desire to create the impression that we should jump indiscriminately and too rapidly from one method to another. While a long siege may bring a number of them into proper requisition, any one deliberately chosen, should be patiently and fully practised for some time. The advantages of the Marshall Hall and the Sylvester method are that they can be thoroughly carried out without cutting the cord. Even Byrd's system can be adopted with the cord attached. That of Schultze, however, requires separation.

Respiration and circulation now being established, to as full degree as the more active immediate efforts can accomplish, we have probably the task of dealing with a very weak, premature, and immature, or otherwise diseased creature. In such cases especially no bathing or washing of the baby should be done at once. Through my whole practice I have adopted with nearly all infants the following method: Immediately after birth, before ligating the cord, the body is laid on a clean napkin sufficiently removed from the mother's discharges of blood to prevent them from soiling it, but without causing tension on the cord. Clean lard is rapidly rubbed over its whole body in plentiful quantity, especial attention being given to the armpits, groins, scalp, and back, where the smegma is thickest. A soft clean cloth is used to rub off the smegma and lard together, and in five to ten minutes, the cord having been ligated and cut, a perfectly clean child is ready to hand to the nurse. No unguent is as good as lard.

Cleansing in this way having been accomplished while jealous care has been meanwhile observed, not to allow it to become chilled, the question arises whether to wrap the immature child in cotton or to place it in an incubator. The incubator being seldom at hand the former must generally be resorted to as a temporary expedient, and where the infant is near full term, or is not too feeble, it may be a sufficient resource throughout.

The accoucheur should always have in his obstetric bag enough absorbent cotton for this purpose. The best way to apply it is to lay down a good thick layer, long enough to reach from the arm-pits to the buttocks, and wide enough to envelop the body of the child. On this at right angles should be laid four narrower layers, two above and two below. When the baby is put on this bed, the two narrow layers are first brought forward over the scapular regions, so that their front ends rest on the chest, when the large layer is brought round the body and lightly run over with a narrow bandage, or fastened by tapes, care being exercised that there is no tight binding. The legs and feet are then separately wrapped in the lower projecting layers, which are secured by a bandage. Lastly the arms are separately enveloped. By pulling away soiled tufts of cotton, and replacing by others the toilet of the infant can be easily and expeditiously made. Artificial heat must be furnished by hot bottles or hot water-bags.

If an incubator is determined on no expensive apparatus is essential. A little mechanical ingenuity, with the instructions of most textbooks on the subject, will help one out.

The feeding must be very carefully managed. The child may be too feeble to nurse from the breast, even though such food were available. Drawing the milk with a breast pump and feeding with a dropper or spoon, in about half-ounce quantities can then be resorted to, or a mixture of whey and milk may be used in about the same quantity, to begin with. Much patience and skill are often required before the proper article for an artificial food is finally found, and before the limits of the child's digestion are fully learned. This subject is too extensive to elaborate within the limits of this paper, and my hearers are referred to the textbooks for its study.

There remains but one other phase of the treatment in such cases that I wish to discuss. With all due care as to warmth and feeding, and other points in hygienic regulation, the use of drugs may also be required. In spite of all the faithfulness he may have exercised in bringing about resuscitation, on his first visit to his lying-in patient, the doctor occasionally finds instead of normal quiet deep breathing, that every breath of the child is accompanied by a feeble moan, or a slight sigh. The pulse is almost imperceptible, and the skin and lips are ashen-gray or slightly dusky. When the child is handled, it either does not cry at all, or there is only a plaintive and pitiable sound. He determines on some stimulation. Under such circumstances I have found the most gratifying results from the administration of atropia or nitroglycerin. The ordinary hypodermic tablets, which every one carries in his cases can be used for preparing the medicine, in such a way that each teaspoonful of the atropia solution contains from $\frac{1}{30000}$ to $\frac{1}{20000}$ of a grain, while the trinitrin solution should contain a similar fraction of a drop of the 10% solution. A dose of each or of one or the other may be given, and its effects watched. Ordinarily, it is repeated from two to six times in the 24 hours. Improvement in the complexion, the pulse, and the respiration can often be noted within an hour of the first dose, and can be maintained by judicious repetition till the powers of nature rally. It is especially this point that I wish to emphasize, as I am not aware that this medication has been anywhere advocated. I am fully satisfied that it has materially assisted me in a number of instances of this kind in tiding over very critical hours and days. The recognized physiologic action of both these powerful drugs may be invoked, to explain their usefulness in enabling a weak heart to gain power, and lessening the resistance in a collapsed lung, and incompletely expanded systemic capillaries. But theory aside, let me ask at your hands a careful trial with the hope that you may find good results.

OTITIS MEDIA IN CHILDREN AND ITS TREATMENT.*

By H. V. WÜRDEMAN, M.D.,

of Milwaukee, Wis.

Ophthalmic and Aural Surgeon to the Trinity Hospital, to the Milwaukee Children's Hospital, to the Milwaukee County Hospital for Chronic Insane; Professor of Ophthalmology and Otolaryngology Milwaukee Medical College; Ophthalmic and Aural Surgeon to the Dispensary; Managing Editor of the *Annals of Ophthalmology*; Associate Editor to the *Ophthalmic Record*; First Vice-President Wisconsin State Medical Society; etc.

At the risk of being deemed dogmatic, I shall endeavor to be as forcible as may be consistent with the deliberations of this association. Perhaps I may lay

myself open to criticism for my positive language, but this paper is a protest against unnecessary and sometimes culpable ignorance, and it is not the vaporing of one narrow mind, but the outcome of well-substantiated facts. "How long, Lord, how long," we that know, may well exclaim, "How long will it be before the average intelligent citizen will recognize the seriousness and importance to life of inflammation within the ear?"

I have been told time and time again by otherwise well-informed people that they "thought nothing of a discharging ear;" and by physicians of the first class that they "could not get people to pay any attention to discharging ears, especially in the case of children;" "paid no attention to the ear;" "let the ear-drum break of itself;" "never made a practice of looking at children's ears when sick with fever, unless their attention was especially directed to it," etc. This is certainly a strange state of affairs, for surely pediatrics is a specialty of the general practitioner, and a very large proportion of children have otitis media. Indeed, otitis is mainly a disease of early life, as is evidenced by the average age of patients with this affection in aural practice. Perhaps this may be explained, as does MacEwan,¹ by the reason that aside from a certain proportion of cases that heal spontaneously or by treatment, the obscure and oftentimes unrecognized complications of the disease kill the patient before maturity. In regard to the danger to life from suppurative otitis media I voice the opinion of all otologists and surgeons when I repeat the remark of MacEwan, who says: "I would sooner have a charge of dynamite in my ear than a drop of pus." It is our duty as members of a benevolent fraternity, tired of it though we may be, to educate the public as well as ourselves in this as in other matters of health.

Most of the diseases of infancy are certainly due to definite bacterial infection arising from the pharyngeal postnasal chamber, distributing the infection to the middle-ear, the brain, the lungs, the stomach, and the intestines. It is, therefore, beyond question that the practitioner of medicine should be fully qualified to treat all ordinary diseases of the upper air-passages, and to take charge of that very common affection of children—acute otitis media—without the necessity of referring to an otologist. If properly treated, and seen early enough, acute inflammation of the middle ear seldom or never results in chronic suppuration, and I state with all the emphasis in my power that chronic suppuration of the middle ear is positively the result of either neglect, improper or insufficient treatment. (The exceptions to this rule are so rare that I can be dogmatic on this point.) In a very large proportion of cases the fault lies with the patients or the parents, and it is only fair here to state that I have many times had the opportunity to observe in consultation the most approved scientific style of treatment by the hands of the family physician.

Even to one whose daily work is among aural patients, recent statistics are astonishing: Barth,² of Leipzig, found that out of 600 infants ill with various affections, 80% were found to have a lesion of the middle-ear.

Von Tröltsch³ found in examining 47 petrous bones taken from unselected children, that the middle ear was normal in only 18; 29 ears showing varying degrees of purulent or mucous catarrh. Schwartze found the tympanum filled with pus in 2 out of every 5 examinations. Wreden found a normal middle ear in only 14 out of 80 cases in children. Perhaps the subject is most

* Read before the Wisconsin State Medical Society, June 21, 1900.

prominently brought before you by quoting the table of Ponfick,⁴ who made 100 consecutive autopsies of infants, finding the ears normal in only 9 cases, there being unilateral otitis media in 13, and bilateral in 78. This table and the importance of the subject was most forcibly called to my attention by an able article by E. H. Pomeroy,⁵ of Calumet, Mich.

PONFICK'S TABLE.

Ponfick's attention to the subject was drawn by observation of his own children who had been dangerously ill with gastroenteritis: the symptoms became alarming in spite of the most careful attention of himself and colleagues and increasingly so until the sudden amelioration which was simultaneous with the discharge from the ear. The improvement in the gastroenteric condition continued until there was a cessation of the discharge from the ear, then came a relapse of the gastroenteric symptoms very gradually and apparently in connection with some changes or faulty preparation of the food. The change for the worse was so gradual and so naturally ascribed to the faulty food that the discharge from the ear was well-nigh forgotten, until it recurred and with it again a pronounced amelioration of the gastroenteric symptoms. This happened not only with one child, but with two or three in the same family. It impressed Ponfick so much that he, with his associates, observed carefully the condition in the first subsequent 100 autopsies of children under three years of age. The results of these necropsies are embodied in what will be now designated Ponfick's table, which contains some most astonishing presentations of facts concerning not only gastroenteritis but many other

conditions in infantile mortality. This table and paper are thoroughly discussed in Pomeroy's article.

At our meeting in 1897 I went over some of the same ground in a paper upon the "Indications for Paracentesis of the Membrana Tympani in Otitis Media Acuta," which seemed to excite some interest and discussion and its publication was noticed elsewhere in a number of medical journals. I then said that from the point of view of a modern otologist a discussion of the reasons for early opening of the drumhead in otitis media almost seemed superfluous reiteration. Since that time, however, I have had several hundred cases of otitis media, both acute and chronic, in a very large proportion of which more or less previous treatment had been done by other physicians, and in not one of which had there been a paracentesis made at the proper time. Most of these have come after spontaneous perforation had taken place. Those, however, who were so fortunate as to have applied for treatment early in the course of the disease before infection of the deeper structures had taken place and before the drumhead had burst, recovered in a very short time, the duration of the average case being less than a week. At that time I gave the following indications:

1. Earache is but a warning of perhaps dangerous disease, the pain of which may be masked by opiates to the ultimate risk of the patient's life.

2. If the drumhead is much reddened or bulging, or if fluid is detected, it is advisable to incise the membrane at once before it bursts, as the character, location, and extent of the tissue-destruction is thereby limited.

3. Pain is relieved at once by the paracentesis; the course of the disease is shortened, the symptoms mitigated, and sequelae prevented by this and appropriate after-treatment.

4. If the case is seen after spontaneous perforation, the hole in the drumhead will often be found to be too small or poorly adapted for proper drainage, and it may be advisable to enlarge it by paracentesis.

5. The little operation gives but temporary pain, and if the physician does not make too much of a show, will be tolerated by any patient, who will be thankful for the relief afforded his symptoms.

6. Meddlesome after-treatment should be discouraged, as when the diseased part is protected from further infection, and the discharge not too frequently removed, the case will usually run a mild course.

The canal should be wiped dry and rendered aseptic by sublimate or boric wash, the paracentesis done under sufficient illumination by the head-mirror and speculum, which should be in the hands of every practitioner, who should not hesitate to perform the operation in any case where an otologist is not available. A wick of iodoform gauze should be placed in the canal, to be removed not oftener than twice a day for gentle removal of the discharge by gentle syringing with warm boric-acid solution, after which the canal is wiped dry, another wick of iodoform gauze inserted, and absorbent cotton placed in the canal to exclude the outer atmosphere. Attention to the immediate causes of the middle-ear affection should be given, general symptoms met by phenacetin, atropin and quinin, the bowels moved by calomel and salines, and the nose and throat sprayed by warm alkaline solutions for cleansing purposes and the nasal irritation and intumescence relieved by camphor-menthol or other appropriate spray.

In order to place before you the advantages of early paracentesis and the above described treatment, in my

experience, I cite brief case histories of cases that have been under my care (in private practice) from January 1, 1900, to May 1, 1900. You will note that the cases of acute otitis media which were seen at an early stage and paracentesis done are very much alike in that immediate relief of the pain and other symptoms was obtained; the duration was very brief and in all cases the drumhead healed with complete restoration of hearing. A second group of cases is made of those in which spontaneous perforation of the drumhead had occurred before applying for treatment. These have likewise done well; in a number the perforation was insufficient to allow of ready exit of the discharge from the middle ear and the perforation was enlarged with much benefit, and in most cases a speedy recovery followed under treatment by gauze drainage.

A third group of cases is made of those in which chronic suppuration of the drumhead attended by necrosis of the walls of the tympanum and ossicles, polypoid and granulation formation had taken place. In a number of these, by minor operative procedures and antiseptic means, healing was obtained; others are yet under treatment. These and those which I place under group 4 are a decided contrast to those in the first and second group. I hold them up to you as "horrible examples." All are certainly the result of neglect, of improper or of insufficient treatment and have only come to the hands of the otologist when warned by painful or severe symptoms that their life was in danger. By going back in my case books for ten years, I could multiply such examples by the hundred and furnish you with many more, such in which the patients were not so fortunate, for death ensued before proper treatment could be applied. I quote you but one example of the latter, which I class under group 5, as but one such case has been under my observation during the last 4 months.

GROUP I.—Cases of *Otitis Media Acuta*, applying for treatment before spontaneous perforation of drumhead occurred. (7 cases.)

CASE 1.—I. L., age 23, Wauwatosa; referred by Dr. Cutler; acute otitis media L.; paracentesis, gauze drainage; duration of discharge after beginning treatment, 5 days.

CASE 2.—L. M., age 14, Milwaukee; seen in consultation with Dr. Reinhard; suppurative otitis media R. and L., following grip; treated by paracentesis, and subsequent dressings by Dr. Reinhard; healing of both Mt. in 2 weeks.

CASE 3.—D. T., age 5, Milwaukee; acute suppurative otitis media L.; paracentesis, gauze dressing; duration 3 weeks.

CASE 4.—C. L., age 50, Milwaukee; referred by Dr. H. M. Brown; otitis media acuta; hemorrhage R.; paracentesis, gauze drainage; duration, 1 week.

CASE 5.—Mrs. W. D., age 30, Milwaukee; referred by Dr. Berger; otitis media acuta L.; was suffering great pain and had taken considerable morphin during last 3 days; paracentesis was done with immediate relief, gauze drainage; discharge ceased in 2 weeks.

CASE 6.—Sr. A., age 43, Milwaukee; acute otitis media R.; paracentesis and antiseptic dressing; duration of discharge 4 weeks.

CASE 7.—Miss T. G., age 25, Milwaukee; referred by Dr. Batchelor; acute otitis media L., several days; no discharge; mastoid tender; temperature 100.5°; paracentesis, free discharge, iodoform gauze drainage; extent of treatment, 1 week.

GROUP II.—Cases of *Otitis Media Acuta*, applying for treatment after spontaneous perforation of drumhead occurred. (8 cases.)

CASE 8.—M. W., age 8 months, Milwaukee; otitis media 2 weeks following scarlet fever; large perforation in R., small

in L.; paracentesis, gauze drainage both ears; duration about 6 weeks.

CASE 9.—Miss E. H., age 25, Green Bay; referred by Dr. Brett; acute suppurative otitis media for 2 weeks R., with facial paralysis of 10 days' duration following grip; retention symptoms; small perforation and bulging membrana flaccida; paracentesis released considerable serum; gauze drainage; membrane healed; no discharge; in 3 weeks all symptoms relieved, except the Bell's palsy, which was nearly well 2 weeks later.

CASE 10.—W. W., age 10, Milwaukee; subacute otitis media; perforation L. Mt.; this is a recurring case; patient has been under treatment, more or less, for the last 5 years, having had a number of attacks of otitis media, each of which has been relieved within a few days by paracentesis and gauze drainage; adenoid and other operations have been done with benefit.

CASE 11.—M. B., age 3, Milwaukee; referred by Dr. Mueller; otitis media acuta R. and L. 1 week; ruptured drumhead one side; double paracentesis R. and L., gauze dressing; healing in 3 days.

CASE 12.—B. B., age 1, Milwaukee; referred by Dr. Mueller; otitis media acuta R. and L.; small perforations both sides; double paracentesis R. and L., gauze dressing; healing in 1 week.

CASE 13.—Mrs. A. H., age 25, Crystal Falls, Mich.; referred by Dr. Darling; acute suppurative otitis media 2 weeks before; slight discharge from middle ear, which ceased after paracentesis and 1 dressing.

CASE 14.—Mrs. C. M. F., Mt. Clare, N. J., referred by Dr. Bradfield of La Crosse for simple dressing for an acute otitis media; referred to Dr. Allport, of Chicago, and Dr. Knapp, of New York, as she was on her way home.

CASE 15.—Mrs. T. P., age 45, Milwaukee; acute suppurative otitis media R.; discharge for 4 days; retention symptoms; hyperexia; had been under treatment by a high potency homeopathist; great pain for 5 days; paracentesis and gauze dressing relieved symptoms at once; although patient got immediate relief, she returned but once; subsequent course unknown.

GROUP III.—Cases of *Otitis Media Suppurativa Chronica*. (12 cases.)

CASE 16.—W. G., age 4, Milwaukee; referred by Dr. Jermain; chronic suppurative otitis media; perforation both membrana vibrans R. 6 months; L. 1 month; daily antiseptic dressing; R. healed in 1 dressing; L. within 3 weeks.

CASE 17.—H. O. R., age 35, Milwaukee; chronic suppurative otitis media R. and L. for 7 years; large perforations both membrana vibrans and in both membrana flaccida; very foul discharge; treated antiseptically 3 months; nasal treatment, tonsilotomy; at end of 2 months removed remains of drumhead and ossicle; by antiseptic treatment for 2 weeks discharge ceased; since that time patient has returned for a couple of visits with slight catarrhal otitis media; no odor, hears better than before operation; extent of treatment, 4 months.

CASE 18.—S. H., age 8, Albion, Wis.; referred by Dr. Lord; suppurative otitis media L. 6 months; small perforation membrana vibrans; paracentesis, iodoform gauze dressing; suppuration ceased in 4 days.

CASE 19.—J. P., age 40, Milwaukee; chronic suppurative otitis media R. and L.; large perforations, osseous necrosis; referred to me by Dr. Miles Clark for opinion upon life insurance, this was refused him on account of the unhealthy condition of his ears; no treatment.

CASE 20.—F. F., age 18, Milwaukee; referred by Dr. Wm. Meyer; chronic otitis media with large perforations in the right ear since scarlet fever 10 years before; treatment antiseptic dressing; cured in 1 week; patient was later subjected to considerable operative treatment, straightening of nasal septum and hypertrophic rhinitis; duration of discharge 1 week.

CASE 21.—O. H., age 8, Milwaukee; deaf-mute from suppurative otitis media following scarlatina at 1 year of age R. and L.; jaws locked; sent to Children's Hospital for antiseptic treatment, but was there only 1 day when she was removed by her parents.

CASE 22.—O. H., age 10, Crystal Falls, Mich.; referred by Dr. Darling; chronic suppurative otitis media since infancy,

with perforation both ears; discharge ceased in 2 dressings; this case had considerable adenoids which were removed by operation; duration of treatment 4 days.

CASE 23.—S. B., age 5, Milwaukee; chronic otitis media; perforated Mt both sides. This child had large amount of adenoids; operation was advised, but patient did not return after first examination.

CASE 24.—J. H., age 35, Kaukauna; referred by Dr. Boyd; suppurative otitis media L. for number of years; large perforation; this ear had been "scraped out" by a quack; slight discharge which was relieved by 2 dressings; duration 3 days.

CASE 25.—H. B., age 8, Milwaukee; referred by Dr. Levings; chronic suppurative otitis media R. and L.; large perforations; this condition was due to inflammation following operation for cleft palate 6 years before; duration 3 weeks.

CASE 26.—O. E. P., age 32, Winneconne; had at one time chronic suppurative otitis media with very large perforation membrana vibrans; no discharge for 1 year; no treatment.

CASE 27.—L. P., age 10, Milwaukee; referred by Dr. O'Malley; suppurative otitis media R. and L.; small perforations both membrana vibrans following scarlet fever 8 weeks ago, then when mastoid was swollen and an incision had been made, but no paracentesis had been done, she was referred to me by the attending physician, but was not brought by her parents until 4 weeks later; when she came to me there was hyperexia; both mastoids tender and swollen; foul pus in both canals, but poor drainage; child had considerable adenoids; both mother and child were exceedingly nervous and refused to have the paracentesis done in office, which was advised, and wanted to go to the hospital, but did not report there at appointed time. This case had severe retention symptoms, and should have had paracentesis done at once. I do not know what became of her.

GROUP IV.—Cases of *Acute and Chronic Otitis Media, with Involvement of Mastoid*, necessitating radical operation. (5 cases.)

CASE 28.—H. S., age 48, Milwaukee; acute suppurative otitis media R. 5 weeks; discharge suddenly stopped, due to swelling shut of the external canal; at examination had hyperexia; great vertigo due to severe mastoiditis; side of the head and neck being badly swollen; Stacke-Schwartz operation at hospital; found erosion of bone over mastoid as well as much pus which was passing down the tissue of neck; subsequent drainage; cure of case in 4 weeks.

CASE 29.—J. W., age 54, Dubuque, Ia.; suppurative otitis media L. for many years. I went to Dubuque in consultation with Dr. Gratiot, of that city, finding patient with great vertigo, pain inside of head, hyperexia, and having sudden cessation of discharge from ear; performed Stacke-Schwartz operation on mastoid finding sclerosed temporal bone; cerebral symptoms relieved by operation; wound behind ear closed by first intention; duration of after-treatment 1 month; no discharge from middle ear when I saw him 2 months later.

CASE 30.—Sr. I., age 40, Milwaukee; earache 1 month followed by discharge which suddenly stopped 1 week ago; great pain; much edematous swelling of mastoid, extending into neck; hyperexia; Stacke-Schwartz operation; mastoid as well as antrum found full of pus and granulations; duration 1 month.

CASE 31.—A. W., age 12, Kingston, referred by Dr. Bothwell; grip 4 weeks ago, followed by deafness and pain in ear; no discharge from ear from that time to this date; slight swelling and redness of mastoid; great pain on pressure and hyperexia; child had been steadily running down; Stacke-Schwartz operation showed the mastoid portion of temporal bone to be a mass of granulation tissue, which was readily removed with spoon; rapid amelioration and restoration to health and healing of wound; duration 4 weeks.

CASE 32.—J. L., age 16, Eau Claire; referred by Dr. Lyman; chronic suppurative otitis media sinistra since scarlatina in infancy; large perforation in membrana flaccida, small in membrana vibrans. Despite much treatment by specialists a malodorous discharge persisted, which contained much exfoliated epithelium. Diagnosis of tympanic necrosis was proven by the results of a Stacke operation, which secured drainage, improved hearing, and entirely removed odor from

the secretion, which occurs at times in small quantity and is readily controlled.

GROUP V.—*Otitis Media Suppurative; Mastoiditis; Abscess of Cerebrum; Meningitis; Death.* (1 case.)

CASE 33.—Miss C. L., age 21, Wauwatosa; referred by Dr. Cutler; has been a patient of mine for 10 years, coming for recurring attacks of suppurative otitis media; patient has been extremely neglectful, never submitting to thorough treating, ceasing her visits and presumably each time on account of my advice that she should submit to the small operation of removal of the necrosed ossicles and caries of the middle ear through the canal; this was never followed; at all times there was small perforation of both tympanic membranes. On May 4, 1900, she was brought to me by her mother, having had suppurative otitis media for 2 weeks; both the family physician and another aurist having been in attendance, they having called for me, but for some reason not having obtained me at the time, no paracentesis had been done and treatment had been simple boric acid wash. When I saw her there was hyperexia, bulging of the tympanic membrane, small amount of pus exuded through small perforation on the left side; immediate paracentesis with gauze dressing apparently relieved the retention symptoms, but one week later typical symptoms of cerebral abscess were evident, drowsiness, frontal headache, apyrexia, dyslexia, sensory and motor aphasia, etc.; trephining over the temporal lobe, together with radical mastoid operation, was made; large amount of pus evacuated; patient lived for 1 month after operation, death being due to extension of the necrotic process within the cerebrum; this case might well have been saved by the very simple surgical procedure which had been again and again advised during the previous 10 years. Death 15 years after original otitis media.

The technic of the treatment of suppurative otitis media is so extremely simple and the diagnosis is generally so easy that but little experience renders any practitioner as skilful as the specialist. Every physician should possess and be sufficiently familiar with the reflecting mirror and aural speculum that he can use it for diagnosis at least in his own practice; he should have a paracentesis knife in his pocket-case and use it as freely as he does the hypodermic needle. In a professional experience of nearly 20,000 patients, I have never seen from my own hands or from those of others, any damage done by paracentesis of the drumhead for acute otitis media; whereas its indications are daily met with in the practice of the otologist and in that of the general practitioner so often that he ought to be familiar with this branch of pediatrics and surgery.

The necessity for examination of the ear and care of aural inflammation in all cases of grave disease in children is certainly demonstrated. But my personal experience with other physicians, both as a general practitioner and as an otologist, shows that it is done too seldom. A considerable portion of cases that eventually come to the aurist could have been saved the additional annoyance, detention from business and expense necessitated by the complications following the original earache if they had been originally under scientific treatment by the family physician.

Against Tuberculosis.—The German Department of the Interior has issued instructions conveying compulsory precautions to be taken against the spread of tuberculosis in the Empire, a copy of which has been sent to the Department of State by United States Consul Monaghan at Chemnitz.

A CRITICAL REVIEW OF THE LITERATURE OF MASTOID DISEASE AND ITS COMPLICATIONS.

By SEYMOUR OPPENHEIMER, M.D.,

of New York.

Laryngologist to Bellevue Hospital Dispensary; Laryngologist to University
Medical College Dispensary; Instructor in Laryngology,
University Medical College.

WHILE the year 1899 was not productive of any radical discoveries relating to the better appreciation of mastoid disease, nor were any new operative measures devised for its relief, yet great progress was made in otology and the diagnosis and operative technic were placed upon a firmer foundation by minute and detailed studies. The function of the specialist, his ability to appreciate the slightest details presented by the anatomy and the pathology of the mastoid and its relation to the surrounding structures, the cerebral cavity, the sinuses and larger veins, the temporal bone as a whole and lastly to the individual, is becoming better appreciated and as a result the operative procedures upon this region and its contiguous structures are being performed more by the otologist and less by the general surgeon. During the year many valuable papers have been published bearing upon this subject, and it is my desire to direct your attention to the salient features that seem of import in elucidating some of the obscure points attached to the diseases of this region.

While the diagnosis of acute mastoiditis rarely presents any great difficulties, and in chronic cases consecutive to suppurative processes of the tympanum the well known signs of mastoid involvement are sufficiently evident to indicate operative procedures, yet there are certain cases in which additional aid is often of extreme value. This is shown in a communication by Cozzolino and Barrogo-Ciarella,¹ who call attention to a new and pathognomonic symptom of chronic mastoid empyema; the rapid reappearance of pus after cleansing of the tympanum and also by its always flowing in a single line over the inner wall of the cavity from the posterosuperior to the posteroinferior segment. As no further reports have as yet appeared concerning the practical value of this sign, considerable hesitancy must be expressed before accepting such an equivocal symptom, as it is hardly possible even for the expert to watch the downward flow of pus as indicated by the authors, and further, although we fully appreciate the fact that pus may exist in the antrum for long periods of time without producing general or local symptoms, other than those of a quiescent chronic otitis suppurativa, yet it seems hardly credible that this should be the only sign present to the exclusion of others of better reputation. One would hardly care to open the mastoid upon the evidence of this single symptom.

Bearing on the differential diagnosis of mastoid disease is the valuable paper of Bar² on the similarity of anterior mastoid abscess and furunculosis of the meatus. Although this question of diagnosis is not nearly as frequent as the mere determination of the presence or absence of mastoid empyema, yet I have seen several cases in which the differentiation was most difficult. Where necrosis is confined in greater or less part to the anterior portion of the pneumatic spaces, a fistula sometimes forms and opens into the external canal on the posterior or inferior wall, and but a few millimeters from the meatus. Around the sinus so produced the dermal lining and periosteum become inflamed, and an

elevation is produced resembling, to a most striking extent, a furuncle. The similarity is decidedly more marked when the opening of the sinus becomes obstructed and the local infection is most accurately simulated. The diagnostic features, as given by the author, are of sufficient importance to be quoted in extenso:

1. Early lymphangitis and periauricular adenitis are the rule in furuncular affections of the meatus, and are late and exceptional in purulent inflammation of the limiting cells. This is consequent on the difference between the lymphatic systems of the external and middle ear.

2. Perimastoid edema effaces the retroauricular depression in furunculosis; whereas, in mastoiditis, the depression persists and remains circumscribed.

3. The pharyngeal plexus may become visible through venous stasis, induced by mastoiditis.

4. Spontaneous pains and sensitiveness are more acute in furunculosis; they are less marked in anterior abscess of the mastoid.

5. In inflammation of the anterior cells, facial paresis is sometimes observed, as is also an exaggeration of the sense of taste and a peculiar sensitiveness of the pharynx and the end of the tongue.

6. The bacterial nature of the pus is different in the two diseases.

7. In the absence of any febrile condition, a continuous disproportion between the pulse and the temperature is in favor of mastoiditis.

In addition to these points I would add that the pain is a constant feature of furunculosis, except in a small proportion of diabetic cases in which the tissue breaks down with little or no disturbance of sensation, while in quite a large proportion of purulent affections of the anterior cells there is little pain, and frequently none at all. While in this form of mastoid abscess, a sinus usually exists by the time the patient is first seen and can be readily probed, in my experience this being of the greatest value in the differentiation of the two affections.

The use of percussion in the diagnosis of acute mastoid disease has received considerable attention on the continent, and Eulenstein,³ considering this method of some value, has suggested the following conclusions from a study of 10 cases:

1. By means of percussion (compared with that of the other side) a positive diagnosis of a diseased condition of the mastoid can be made, provided dulness is elicited.

2. Dulness on percussion indicates the presence of a diseased area near the surface of the bone, the degree of dulness depending upon the extent of the area involved.

3. The absence of dulness is no proof that the bone is not diseased.

4. Where other symptoms of mastoid disease are present and there is no dulness on percussion, it indicates that the diseased area is either very small or deep-seated.

5. By percussion we are enabled to recognize mastoid disease earlier, and it is a valuable adjunct to the indications for opening the mastoid.

From a study of 6 cases of acute mastoiditis in which percussion was used as an aid to diagnosis in my hands, it signally was of no service, because light percussion will not elicit any sounds that can be compared with the normal side, and where deep percussion is tried the

pain is too great, so that in the majority of cases the method is impracticable. Further, dulness does not necessarily indicate the presence of pus, as it may be demonstrated in superficial edema of this region without bone involvement. It may also be exaggerated where the bone is sclerosed, or in those cases where the pneumatic cells are few in number or absent near the surface. This was demonstrated in a case recently observed, in which the patient complained of intolerable pain over the mastoid area, swelling of the tip and impairment of general health, with an irregular temperature. Dulness over the entire region in comparison with the normal mastoid was marked, but on opening the process it was found to be normal; the pain being neuralgic in character as proved by its subsequent disappearance, while the swelling resulted from glandular enlargement.

The broadening of the surgical field of the aurist has been but the inevitable outcome of better diagnostic methods, and it can safely be said that many obscure head-lesions are being better appreciated, and their intimate etiological relationship to aural suppuration affords an inviting field for surgical measures presaging relief in a greater proportion of cases than has heretofore been possible. This has been greatly aided by the detailed study of individual cases of mastoid disease and its complications, such an instance being reported by Ler-moyez⁴ of mastoiditis with perforation of the medial plate and consecutive abscess in the neck beneath the insertion of the sternomastoid muscle. This case occurred in an infant following acute otitis media, and while not unique at all, yet the report is valuable as teaching two important lessons, the first being that the serious symptoms of an uncomplicated otitis were the result of excessive treatment, and, secondly, that the presence of a cervical abscess should always suggest a focus of suppuration in some portion of the aural region.

Mastoiditis with perforation of the medial plate, as pointed out a number of years ago by Bezold, is more frequent than generally supposed, and with the deep burrowing of pus, the tissues of the neck become infected, and extensive operative measures are required. Burnett,⁵ in reporting an interesting case of acute mastoiditis with perforation of the medial plate and consecutive abscess of the neck, takes occasion to call attention to the routes by which mastoid and tympanic suppuration are propagated to adjoining regions. Three ways are currently accepted; by the veins, by the lymphatics, and by the direct escape of the pus through a spontaneous opening in the medial plate, this latter being so-called Bezold's mastoiditis. Lewis⁶ and Dunn⁷ report similar cases, showing clearly the possibilities for harm resulting from delayed treatment of simple mastoid inflammation. The former's case was one in which the process was filled with a cholesteatoma, with an eroded area in the floor of the middle cerebral fossa, and another in the wall of the sigmoid fossa. There was an opening along the digastric groove, through which the mastoid was in direct communication with an abscess of the neck. As the patient was 24 years old, and had had a suppurative otitis media from infancy, it clearly becomes evident that the double danger to which she was subjected, both from a suppurative process and a mechanical obstruction to free drainage by the cholesteatoma, should have been removed several years before she was seen by the author. Dunn's case is instructive as showing the extent to which the pus may burrow and extend

in several directions from the mastoid focus. There were pain and swelling over the left ear and a partial facial paralysis, but no middle ear discharge at any time. The mastoid was found infiltrated with pus and granulations, and the patient did well for 10 days, when stiffness of the left side of the neck developed with a swelling over the upper end of the sternomastoid muscle. An abscess was then found lying between the sinus and the inner table of the skull, and following the lateral sinus along its course for about $\frac{1}{2}$ inch and the sigmoid sinus for about the same distance. Following these symptoms, pain on swallowing developed, and finally an abscess in the neck burst into the esophagus. It will be seen, therefore, that following the original perforation of the mastoid, the pus had formed an epidural and subpetrous abscess, and had then burrowed deeply in the lateral cervical tissues, ultimately producing a postesophageal abscess, with the ultimate death of the patient.

Fougeray⁸ calls attention to the frequent occurrence of the spontaneous external discharge of mastoid empyemas, and thinks that such cures by external evacuation of the pus without operative procedure have not been sufficiently reported in the literature. He claims that the most frequent spontaneous openings occur over the antrum, while in other cases the opening is developed lower down in the mastoid surface, and sometimes it occurs in the digastric fossa. A fourth form occurs very rarely, however, and consists of an opening upon the occipital surface, the purulent material traveling by way of the pneumatic cells sometimes found in the occipital bone. He also adds to these varieties a fifth, based upon a case under his care, in which the pus discharged itself forwards into the auditory canal by destroying the wall of the attic and the posterosuperior wall of the osseous auditory canal. While these varieties of spontaneous evacuation of mastoid empyema may be frequent in the clinics of the continent, they are certainly not seen in this country, with the exception of that perforating the medial plate, except when due to some localized expression of a constitutional dyscrasia, as syphilis, tuberculosis and diabetes, and even then one is hardly warranted in claiming it to be the result of mastoid disease, as while this process may be implicated, yet the temporal bone to a greater or less extent is involved in the destructive process.

Of operative procedures upon the mastoid, that of Kuster⁹ has been the only new one of importance, although many modifications of older methods have been published. Kuster calls his method an osteoplastic opening of the mastoid, the method of procedure being as follows: The auricle is drawn forward and an incision made along its posterior border beginning a short distance above the level of the auditory meatus. It then passes around the tip of the mastoid and is carried upwards along the posterior border to the same level where it commenced. The incision is made down to the periosteum and is U-shaped, with the attached portion of the flap above and the periosteum then pushed aside, and following the outline of the flap, a shallow groove is cut in the bone with a chisel. With a broader chisel a thin plate of bone is split off from below upwards, this segment remaining adherent to the soft tissues and the entire flap is turned upwards, leaving the operative field free, the surgeon then proceeding according to the indications present. After all diseased tissue has been removed the flap is replaced,

a small notch being made in its lower part for drainage and the case is dressed in the usual manner. The author reports 9 cases in which he used this method, and he claims it is superior to other methods because there are little resultant deformity, rapid healing and a good opportunity for the tampon in case the sinus or dura are injured during the operation. This last advantage is so trivial as to require no comment, while in other respects the operation is based on lines radically wrong, as it allows of the external closure of the wound with retention of purulent material and there is no opportunity for the parts to heal from within outwards by granulation tissue.

Suggestive of operative procedures upon the mastoid are the following conclusions formulated by Randall¹⁰ upon the study of 100 cases:

1. Wilde's incision is not good surgery.
2. Conservatism and expectancy are in order as long as there is no pus demonstrable outside of the middle chamber.
3. When rational signs of pus are recognized, all temporizing must cease and sound surgical principles must be followed.
4. A clean sweep of all diseased tissue must be made and sinuses must be explored.
5. Have a clean field before you in operating.
6. Good drainage must be established.
7. In chronic cases, it is rarely sufficient to clean out the mastoid alone.

One can hardly add anything to these able conclusions except it be in the choice of instruments and then merely to say that the chisel and spoon should always be used in preference to any method depending upon the trephine, burr and dental engine which have been employed to some extent.

One of the most important questions engaging the otologist today is the determination in advance of any operative procedure of the danger points on the temporal bone, the relation of the sinus to the surface and the nearness of the cerebral fossa to the proposed operative field. While much labor has been spent in seeking external evidences of these points, success has unfortunately not been attained, although general indications such as those mentioned by Okade¹¹ are of value. He concludes from the study of 111 skulls that the anthropological form offers no trustworthy evidence of the presence or absence of the so-called dangerous temporal bone. The relation of the transverse sinus to the field of operation should be looked for, and unusual care taken when operating on the right side; if the mastoid process is unusually small; if the patient has not reached the age of puberty; and more care must be exercised in the case of women than in men. While these indications are but general, yet they present features of value and are necessary in forming part of the foundation for future work in this field.

As the vast majority of cases of mastoiditis are the ultimate result of middle-ear suppuration and the majority of the latter proceed from the infectious diseases of childhood, the paper of Dench,¹² dealing with the mastoid complications of the exanthemata of children, is timely and contains much of value. He considers the treatment under prophylaxis and after the involvement of the mastoid has taken place. Under the former heading the statement is made that in any eruptive fever in which a sudden rise of temperature takes place, which is not explainable by the general condition of the patient, we should examine the ears for evidence

of inflammation. One is inclined to go even further than this and consider that an examination of the membrana tympani should be made in every instance of an exanthematous affection, as by adhering to this rule, many cases of what would undoubtedly result in mastoiditis would be prevented. Should the tympanum be inflamed a free incision should be made from a point just below the tip of the handle of the malleus, upward to the tympanic ring; and if the temperature should be very high, the incision should be extended outward a considerable distance along the roof of the auditory canal, dividing the soft parts to the bone. This will permit the escape of any secretions should they be present and will also relieve the tension which is a prominent factor in the production of pain.

Should the mastoid become sensitive to pressure, the icebag or cold Leiter's coil may be applied, but if not effectual in 48 hours, it should be discontinued. Should there be a discharge from the tympanum, frequent irrigation of the canal with a lukewarm bichlorid solution may be productive of much benefit. Should the case not be seen until a fluctuating tumor has developed behind the auricle, we should immediately operate and even in very young children the mastoid antrum should be opened in every instance. Irrespective of the absence of a sinus leading from the interior of the bone, or of an apparently normal cortex, the bony structures should be entered as we always find in these cases some diseased bone, either in the mastoid antrum or in the aditus. In young children the cranial bones are thin and the infection of the intracranial structures may readily occur through the external surface of these bones, as well as through the tympanic roof, or through the posterior wall of the mastoid antrum; but if the middle ear is thoroughly drained by a posterior opening into the mastoid antrum, subsequent infection of the intracranial structures is impossible. In regard to the radical measures advocated by the author of opening the membrana tympani when inflammation supervenes, it certainly appears that this is too severe, when we have the opportunity to use less radical measures as hot irrigation; and if this and similar means fail after 24 hours, then the delay will in no way compromise the case and if necessary the incision in the membrane can be made. While apparently good results are frequently seen from the simple incision of the soft tissues in mastoiditis, yet these are the cases that return later for a radical operation, when if the primary operation had been thorough, the case would have had no further difficulty. It cannot be too strongly impressed upon every practitioner, that, as Dench well says, even if the mastoid cortex be apparently normal, we must open it and establish free communication with the middle ear.

If one were required to point out any subject in otology in which the greatest progress has been made during the year, he would not hesitate in indicating that of the sinus and brain complications of mastoiditis. While this subject has been receiving more and more attention during the past few years, the study of sinus thrombosis received an added impetus from the classic paper of Whiting.¹³ He divided sinus thrombosis into three stages; the first being characterized by a parietal or complete thrombus, not disintegrated and accompanied by moderate pyrexia and usually the absence of rigors. In the second stage, there is disintegration of the clot, with resultant systematic absorption; frequent rigors and pronounced fluctuations of temperature. During the third stage

disintegration has progressed, with systemic absorption, accompanied by rigors, rapid and great fluctuations of temperature and central or peripheral embolic metastasis, terminating usually in septic pneumonia, enteritis or meningitis. The author further remarks that the diagnosis in the first stage is seldom made preliminary to the operation for mastoiditis, and the only safeguard against the second stage is to operate immediately upon the recognition of the first. The transitional period between the two stages is usually brief and its completion is commonly announced by a sharp rigor.

As described by Whiting in performing the operation for sinus thrombosis, the usual mastoid incision is made extending from 1 inch below the tip of the process, to a point $\frac{1}{2}$ inch above the temporal ridge. A second incision is than made beginning at the center of the first and extending backwards 2 inches or more towards the occipital protuberance. The pneumatic cells and antrum are opened, the sigmoid groove is quickly entered with a curet or rongeur and the thrombus is eviscerated, bleeding being controlled by gauze-packing. At the moment the sinus wall is opened, the foot of the operating table should be elevated, to reduce the chance of admitting air to the sinus and to maintain the equilibrium of the general intracranial fluids, which might be seriously disturbed by suddenly inducing anemia of the brain, from the profuse bleeding from the sinus.

When symptoms of septicemia develop during an attack of mastoiditis, the indications of sinus involvement are, as already mentioned, fairly well established; at all events, however, it should be the invariable rule to operate immediately. An exception to this is found in the report of 2 cases by Stanculeanu and Baup,¹⁴ but this, of course, does not in any way invalidate operative procedures. Both these cases terminated fatally and the necropsy showed no lesion of the sinus nor of any other portion of the venous system, but there were fatty changes in some of the viscera and an extremely virulent streptococcus was found in the blood. While the bacteriology of mastoiditis and its complications has received some attention, yet much remains to be done, it now becoming better known that the pneumococcus presents an almost insuperable barrier to medicinal treatment of middle-ear suppurations in which this organism is intimately concerned, and the tendency to mastoid complications are greater in such instances than is seen with almost all the other organisms.

When a thrombus has once formed in the sinus and becomes infected, pyemic symptoms are inevitable; that pyemia the result of mastoid abscess may occur without sinus infection I believe to be possible, although this is combated by Meier,¹⁶ who opposes the view that there are several varieties of otitic pyemia, such as that with thrombus of the lateral sinus; pyemia without thrombosis of the sinus, where presumably a thrombus of the small veins of the petrous portion exists, and finally where the infection is carried through the lymphatics. In his experience he found on careful examination a thrombus in every instance and believes that it is frequently overlooked and is often situated low down, even in the bulbar portion of the jugular vein, the sinus proper being open above. An exploratory puncture is of no value, for free blood may be obtained even when a thrombus is present.

As shown by Knapp,¹⁸ the prognosis of sinus thrombosis with articular metastasis is better than when the

emboli lodge in the pulmonary area. An interesting case illustrative of the latter is reported by Greene¹⁷ in which the symptoms simulated typhoid-pneumonia. There were pain in the left ear, face and side of head and great swelling of the neck and throat. Chills, fever, emaciation, insomnia and constipation were prominent while the mastoid was edematous and contained a small amount of pus. In addition there existed abscesses of the chest, pharynx and neck, and a brain abscess was also evacuated, the patient dying in a few weeks from cerebritis. A similar case, but presenting the agreeable contrast of recovery, was reported by Payne,¹⁹ in which for acute endomastoiditis a Schwartze operation was performed, but the temperature continued high, cough and rigors developed and suppuration became so abundant that an extensive Stacke operation was done. The temperature varied from 96 to 106° for nearly two weeks, when a large slough, consisting of a portion of the dura mater, presented at the wound. The exact site of the lung abscess was not determined, but its existence was shown by the patient coughing up a large amount of foul pus. After this the case progressed to complete recovery. It was well demonstrated by this case that although the prognosis may be practically hopeless, yet prompt surgical intervention will in many instances save the life of the patient.

DISEASES OF THE EAR IN RELATION TO GENERAL MEDICINE.¹

BY NATHAN G. WARD, M.D.,

of Philadelphia.

Otolaryngologist to St. Agnes Hospital, Assistant in Laryngology
Jefferson Medical College Hospital.

DISEASES OF THE EAR IN RELATION TO GENERAL MEDICINE.

Affections of the ear are still looked upon by the laity and by many otherwise very able physicians as being of but little consequence. The general opinion prevails that the child who frequently suffers with ear-ache will outgrow it; that purulent discharge from the ear is a slight ailment, not to be interfered with for fear that if checked it will affect the general health, and that beginning deafness in the adult is beyond the reach of therapeutic agents.

The anatomical structure of the ear, its proximity to, and communication with, other most important structures plainly indicate the serious consequences that may follow inflammation of that organ.

The mucous membrane lining the tympanum is in-

¹ Read at a meeting of the Associated Physicians and Surgeons of the Charity Hospital, Philadelphia, February 8, 1900.

separable from the periosteum and serves its function in supplying nutrition to the bone beneath, hence any severe or continued disturbance in the nutrition of the soft parts must necessarily lead to loss of nutrition and caries of the adjacent bone. Necrosis of bone in any part of the body is to be much feared. The disease-process is not simply local, but often causes grave systemic complications, as thrombosis, embolism (both of which may be infective), metastatic abscess, general cachexia, and pyemia. Still more momentous is necrosis in the tympanic cavity on account of its proximity to the internal carotid artery, internal jugular vein, lateral and superior petrosal sinuses, the brain, and its meninges, from all of which it is separated by a thin delicate and sometimes even deficient layer of bone.

Inflammation of the ear more frequently complicates those diseases that are associated with catarrhal affections of the upper respiratory passages, but is by no means limited to such.

The importance of recognizing the disease in its early stage is emphasized by reference to some of the mistaken diagnoses as given by Frothingham.²

Disease Present.	Diagnosis.
Acute otitis media followed by meningitis.	Unrecognized.
Acute mastoid disease.	Cellulitis.
Furuncle of auditory canal.	Mastoid disease.
Acute otitis media.	Neuralgia.
Otalgia dentalis.	Gathering in the ear.
Acute otitis media, both ears.	Overlooked in the left.
Polypus from Shrapnell's membrane the unrecognized cause of head symptoms.	Head trouble due to change of life.
Polypus in ear.	Chronic catarrhal disease.
Acute otitis media with bulla of drum.	Malignant growth.
Dried desquamated epithelium in the external canal.	Ossicles coming out.

MUMPS.

The complications or sequelae of mumps is by metastasis—usually orchitis. A similar condition has been reported in the ear. In this, however, there are no acute inflammatory symptoms. There are sudden deafness, unilateral and usually permanent; giddiness and disturbance of equilibrium. Sometimes there is a loss of consciousness. The condition is not fatal, therefore the pathological alterations are not known. It is probable, however, that there is a sudden extravasation of serum into the labyrinthic structures. There is no relation between the severity of the attack of mumps and the ear manifestations. Some of the cases reported were very mild in character.

In *measles* the ears are affected, not always producing suppuration, but causing hyperemia and congestion of the tympanum. The eustachian tube, however, is still more frequently involved and in many cases is affected before the eruption appears on the skin. Blebs have formed beneath the outer layer of the tympanic membrane.

Diphtheria and *scarlet fever* more frequently produce suppuration of the middle ear than other diseases. Sudden deafness may be caused by congestion and exudation in the mucous membrane and collection of fluid in the tympanic cavity, preventing the transmission of sound-waves. Ulceration and necrosis of bone frequently follow even to the extent of entire

destruction of the eustachian canal, both cartilaginous and bony, the ossicles and cochlea. When the process is less severe the tympanic membrane usually ruptures and the acute condition passes into that of a chronic suppuration with continuous or intermittent discharge.

In those cases in which the diphtheric process involves the nose and nasopharynx it is most likely to extend into the middle ear.

Burnett¹⁵ reports such a case. Lommel¹⁷ states that "disease of the organ of hearing and particularly of the middle ear, occurs with uncommon frequency in true diphtheria. We may therefore almost establish the rule that otitis media forms a part of the clinical picture of diphtheritic inflammation of the respiratory tract." In 25 successive autopsies of individuals who had died from diphtheria 24 showed involvement of the middle ear (96%). In many the eustachian tube showed no pathologic changes, and in others the tube was but little changed. The bacillus of diphtheria has been found in the aural discharge after clinical symptoms had disappeared. Sudden deafness has been reported during convalescence, at the time of other palsies and albuminuria. The lesions involve the auditory nerve or center and is of the same nature as that which gives rise to the more frequent diphtheric paralysis. In a case reported by J. C. Wilson¹⁹ the deafness continued in spite of all treatment, while in other cases rapid recovery was reported.

INFLUENZA.

The otalgia of influenza, during the acute manifestations of the disease, may be due to inflammation and swelling of the tissue and glands of the faucial region, the pain being referred to the ear, or there may be serious involvement of the tympanum, varying from simple occlusion of the eustachian tube to a suppurative otitis media with mastoid involvement. Often the perforation in the membrana tympani is very small and needs to be enlarged by incision to afford free drainage.

Dench²¹ reports cases of influenza with involvement of the labyrinth or auditory nerve-trunk. He thinks the disturbance is angioneurotic in character.

A serious involvement, and one usually not recognized during its early progress on account of the absence of symptoms referable to the ear, is that of a slow, progressive inflammatory process with organization of fibrous tissue in the middle ear causing adhesions of the ossicles and thickening of the Mt., producing chronic progressive deafness. Symptoms of this process are not manifest for from six months to a year after the attack of grip.

RESPIRATORY TRACT.

Nose.—On account of the intimate anastomosis between the bloodvessels and lymphatics of the nose, nasopharynx, and ear, any condition that obstructs nasal breathing, as constant hyperemia or congestion of the mucous membrane, polyps, hyperplasia of the turbinates, and foreign bodies, will cause congestion of the eustachian tube and middle ear by interfering with the return blood.

Lederman²² records a case of a girl, 3 years old, who had a running ear for 2 months, which appeared one month after a purulent nasal discharge. A coffee bean was found in the nostril. After its removal all the symptoms disappeared, and in 4 days there was no

trace of pus in the ear, and in a week the nasal secretions were almost normal.

Nasopharynx.—Ear involvement is aided in all diseases in which the patient lies in bed, especially on the back. This position favors retention of secretion in the nasopharynx and impedes drainage from the ear through the eustachian tubes.

Allport²³ reported a case of acute myringitis following nasopharyngitis. Three large bullæ formed beneath the epiderm of the Mt. They did not communicate with each other, nor penetrate to the internal surface. Myles²⁴ has seen cases in which adhesions between the orifices of the eustachian tube and the pharyngeal wall converted the fossa of Rosenmüller into small pockets. The adhesions and thickening caused partial closure of the orifices and produced stuffiness and fulness in the ears, slight buzzing, and a deep, dull pain over the ear with lessened acuity of hearing, all of which were relieved by breaking up the adhesions and removing small masses of lymphoid tissue. Myles thinks the bands were the remains of old adenoid tissue.

LUNGS.

Croupous and catarrhal pneumonia and catarrhal bronchitis, especially when the apex of the lung is involved, makes chronic otitis media worse, and often causes a recurrence in those who have had it before.

Meltzer²⁵ has seen several cases of lobar pneumonia in children in which the earliest symptoms were earache and high fever. The earache ceased gradually after the full development of pneumonia.

Straight²⁶ reported cases of chronic otitis made worse by catarrh of the lung apices. The ear-symptoms improved or entirely disappeared from the internal administration of creosote, and without any local treatment.

ALIMENTARY TRACT.

The pain produced by inflammation in the region of the tonsils and of the lymphatic glands behind the posterior pillars of the palate is often referred to the ear, the patient not complaining of any throat symptoms.

Diseases of the alveolar process or teeth produce various ear manifestations, viz., "an aching fulness which seems something like a gathering, a heaviness or sense of weight, severe earache, and lessened acuity of hearing." (Flagg.) The conditions producing these symptoms are: Eruption of teeth—especially when impacted,—dental caries, pulpitis, pericementitis, and excementosis (or, as it was formerly termed, dental exostosis), and alveolar abscess. The ear may be actively inflamed from these causes. Flagg³⁰ reports a case of a lady who had been completely deaf in the left ear from excementosis. After extraction, improvement began in 2 weeks, and in 10 weeks she could hear ordinary conversation distinctly. Similar troubles have been caused by filling root canals in which the substance used is forced out of the apex at the alveolar process, or where a metallic filling beneath the edge of the gum is left rough with sharp angles to cause continual irritation of the gum.

Gastrointestinal disturbances, especially in children, may be associated with pain and congestion of the tympanum.

E. H. Pomeroy,⁵³ reports 5 cases in which there were no ear manifestations, all symptoms gave evidence

of severe gastrointestinal disturbances. In the first the ear involvement was unsuspected during life and was only revealed at the autopsy. Acting upon the knowledge gained by this case, in the succeeding 4 cases he punctured the Mt. A few drops of fluid escaped in each instance, followed by immediate amelioration of the intestinal symptoms and a speedy recovery.

Toynbe cites cases of total deafness from the exhaustion caused by attacks of diarrhea, cholera, or the administration of violent purgatives.

Typhoid fever may give rise to temporary deafness due to congestion and lowered nervous tone, during the high temperature period, which usually passes away during convalescence. In many cases severe otitis develops, ending in suppuration, perforation of the Mt. and necrosis of the bony structures.

In *tuberculosis* the ear is probably more often primarily affected than is usually supposed. It is frequently involved during the latter stages of pulmonary tuberculosis. In scrofula the enlarged glands interfere with the venous and lymphatic circulation and cause a lowered resistance in the mucous membrane and thus favor throat and ear affections.

Syphilis.—Syphilitic manifestations in the ear, as in other parts of the body, may be deceptive, varying from otalgia, due to ulcerations in the nasopharynx, to congestion and inflammatory exudation in the Mt. and about the head of the malleus even to necrosis involving the whole of the petrous portion of the temporal bone. Sudden deafness may occur during the secondary stages and is probably caused by exudation in the labyrinth.

In hereditary syphilis the symptoms appear near puberty, both ears are usually affected.

Rheumatism.—Acute otitis media has preceded attacks of acute articular rheumatism. Chronic progressive changes leading to deafness may take place, advancing so insidiously as to escape notice until permanent damage has been done. This is as often found in those who suffer from uric-acid diathesis as in the chronic rheumatic.

THE NERVOUS SYSTEM.

Inflammation of the tympanum may be caused by extension from the cranial cavity as in meningitis. In locomotor ataxia the fifth and eighth nerves are often affected. Collet⁵⁶ gives the pathological changes present as atrophy of the nucleus in the floor of the fourth ventricle, and of the nerve-trunk producing nerve-deafness and sclerosis of the inner wall of the tympanum and of the Mt. Asher⁵⁸ reported a case of serous exudative inflammation of the middle ear following intracranial resection of the second and third branches of the fifth nerve, from the foramen ovale and rotundum up to the gasserian ganglion which was not exposed. The ear symptoms appeared in 3 weeks after the operation and in the ear corresponding to the side operated upon.

In those whose acuity of hearing is impaired, mental excitement and worry increase their disability and may cause temporary or permanent deafness.

CIRCULATORY SYSTEM AND BLOOD.

Congestion of the ear in cardiac insufficiency occurs as in other parts of the body. Anemia and congestion produce tinnitus. Hemorrhage in the middle ear and even in the labyrinth producing infarction are sometimes present in leukemia. Atheroma of the blood-

vessels may take place in common with other general senile changes.

KIDNEY.

In all kidney diseases in which there is deficient elimination the ear may become affected. In parenchymatous and interstitial nephritis there may be aural hemorrhage, but more frequently tinnitus and deafness.

Morf⁶² reviews the subject very extensively and concludes there are: "Irritation of the acoustic nerve filaments from retained substances in the blood due to nonelimination by the kidneys; increased arterial tension, and serous exudation in the labyrinth, corresponding to the dropsy in other parts of the body." Morf cites a case reported by Rosenstein in whom the hearing and other ear symptoms varied with the general dropsy—better as the general dropsy disappeared, and vice versa. Morf reports a case in which the loss of hearing and visual disturbances were the only symptoms that led to his examining the urine and the discovery of the kidney disease. If it be proven that inflammation of the kidney produces such marked effect upon the ear it may partly explain the frequency of otitis as a sequel to scarlet fever. Voss⁶² says: "The connection indeed is so intimate that the progress of the nephritis may be followed by the course of the otitis. Deafness and pain in one or both ears may follow, or even precede, a diminution of urine. The discharge varies directly with the intensity of the albuminuria."

GENITAL ORGANS.

Redness of the membrana tympani occurs in some cases during the menses. P. Bourlon⁶³ collected 23 cases of menstruation through the ear. The hearing was never affected by the hemorrhage. In some cases it was bilateral. It does not recur with any regularity and is usually preceded by heaviness, pain in the head, vertigo and tinnitus. In most cases the hemorrhage from the ear ceased as menstruation was reestablished.

Pritchard⁶⁴ reported a case of a woman four months pregnant, who complained of giddiness, vomiting and vertigo. The attacks were followed by transient deafness. The same condition was present during a previous pregnancy, ceasing after delivery.

Toynbe⁶⁵ reported a case, aged 40, of nervous temperament and rather anemic, who consulted him in 1850, on account of complete deafness. She had married 10 years previously in India and had always heard well until her first confinement. She suffered a great deal from exhaustion; this was followed by a great degree of deafness, so that she could scarcely hear even when the voice was much raised. As she recovered and regained her strength the deafness was much relieved, though her former acuity of hearing was not fully regained. During each successive confinement in India, amounting in all to four, the deafness greatly increased, and after each recovery became more permanent until on the last occasion she remained totally deaf and was obliged to have recourse to signs. Indeed, she had never heard the voices of her younger children.

EYE.

Eye-manifestations are not present as long as the ear disease is limited to the middle ear and mastoid cells, but there are eye-symptoms in about 50% of the ear cases complicated by intracranial invasion of the inflammatory process. When present it is not pathognomonic of such a complication, but only confirmatory.

The affections of the eye reported as a result of ear disease are: Swelling and puffiness of the eyelids, conjunctivitis, keratitis, retinitis, neuroretinitis, papillitis, choked disc, and, in rare instances, paralysis of some of the external muscles. Inflammation of the lids, conjunctiva and cornea may be caused by infection conveyed by the hand or handkerchief from the ear to the eye.

As to the frequency of papillitis or retinitis, Milligan⁶⁶ quotes Gradenigo as follows:

Extradural abscess, uncomplicated.....	41 %
Septic thrombosis of sinus, simple or complicated with extradural abscess	59.6 %
Cerebral abscess, simple or complicated with sinus thrombosis	57.9 %
Cerebellar abscess, simple or complicated with sinus thrombosis.....	60 %
Leptomenigitis, simple or complicated with sinus thrombosis	48.9 %

DRUGS.

Overdoses of quinin and the salicylates produce marked tinnitus by causing congestion within the ear. Ramsay⁷⁶ reported a case of syphilis in whom the left ear previously healthy became filled with a serous fluid during acute iodism caused by the administration of KI. As soon as the iodid was withdrawn the deafness and fluid disappeared with the other symptoms of iodism.

Shastid⁷⁶ reported a case of chronic catarrhal deafness in whom each dose of belladonna caused dryness of the throat and nose with increased deafness.

In a case of my own, homatropin hydrobromate was ordered as a mydriatic for refraction. During its action the deafness was much more marked and after its effects had passed off the hearing acuity returned to its former condition.

SYSTEMIC RESULTS FROM DISEASES OF THE EAR.

The more frequent are those from extension by contiguity of tissue, *e. g.*, meningitis, thrombosis in the venous channels, abscess beneath the dura, in the cerebrum, or cerebellum; pyemia, facial paralysis and involvement of the mastoid cells. As a matter of fact the latter is the most frequent, and it is from this source especially the other complications arise. The mastoid cells open into the tympanum posteriorly and are easily involved by extension. This often results from no treatment at all or is hastened by improper treatment, as by forcible and frequent syringing of the ear in chronic discharge. In children the mastoid cells lie more nearly horizontal than in the adult, hence drainage is less perfect. This accounts in part for the more frequent involvement of the mastoid in children. In all severe cases that do not readily yield to treatment it may be safely said there is necrosis of bone. The symptoms of mastoid involvement are: Intense pain in the side of the head, swelling or edema over the mastoid, discoloration, tenderness, or acute pain on pressure behind the external auditory meatus just behind the auricle, bulging of the tympanic membrane or depression of superior or posterior wall of the external canal just in front of the tympanic membrane.

In the child these symptoms may be less manifest on account of his inability to make known the nature and seat of pain. When closely observed the child will be seen to roll the head from side to side, to put the hand to the side of the head affected and to scream

when attempting to nurse on account of the pain caused by swallowing. In any case, with the history of long-continued discharge from the ear which has ceased suddenly, accompanied by rigors and subnormal temperature, brain abscess is almost surely present.

In many cases the severity of the cerebral symptoms are out of all proportion to the pathological changes in the meninges and brain as revealed at the autopsy.

Epilepsy has occurred from ear disease and was relieved by proper treatment to the ear.

In many of the diseases enumerated the ear trouble is not due directly to the systemic malady, but the latter weakens the resistance of the organisms and the patient takes cold, which the more easily extends to the ear and produces much greater damage than is general in ordinary colds. In not a few of these cases the ear manifestations are a recurrence of a former malady, which may have been years ago and at first forgotten until closely questioned, instead of a primary disease of this organ.

In records of autopsies revealing these ear involvements there are no histories depicting the condition of the ear as revealed by careful examination before death. This, of course, is due to the want of symptoms pointing to that organ, but it at the same time suggests possible manifestations that are interpreted as pointing to other organs that would indicate ear involvement if rightly understood.

The line of progress for the future is plain. Let the general practitioner and the specialist work together, observing in detail all manifestations of ear involvement and search diligently for them even when not so plainly marked. In autopsies, dissections of the temporal bone should be more frequently made and the findings compared with symptoms before death. By so doing great advances will be made, and diseases of the ear that are now not recognized will be readily diagnosed and successfully treated.

INFANTILE COLIC AND COLIC IN INFANTS.*

By H. ILLOWAY, M.D.,

of New York.

Formerly Professor of Diseases of Children, Cincinnati College of Medicine and Surgery; Formerly Visiting Physician, Jewish Hospital, Cincinnati; etc.

For the whole period of his existence upon this mundane sphere, the human being is liable to colic. It may lay hold of him at any time, in youth, in manhood, in hoary old age, bend him double, twist him into knots as if he were a practising contortionist. It is, however, at the earliest period of his life—almost with his entrance upon this nether globe—that it seizes upon him with greatest violence, holds him tenaciously in its grasp and seems to vent, as it were, all its malice upon him. It is the youngest infants that are most subject to this ailment; it disturbs their rest, breaks in upon their angelic slumbers, and causes them to make the welkin ring with their outcries. Truly they suffer, and those about them are made to feel the weight

*Read before the Pediatric Section of the Academy of Medicine at the Meeting, Thursday, January 10.

of their woe. The good mother, the kindly nurse, are driven to distraction in their efforts to alleviate baby's sufferings and frequently, for long periods, know no rest.

The seizures may be sporadic, that is occurring at long and various intervals and always the result of some well-defined sin of omission or commission in the care or the feeding of the infant.

Or they may manifest themselves from the second or third day after birth, usually the latter, and continue throughout a longer or shorter period of time, recurring with varying frequency throughout the days and nights of that time. It is this latter form which has been designated by the older writers as "infantile colic," and to it only this distinctive designation truly applies. Such infants, in the language of the laity, are "colicky."

The duration of this colicky period varies, depending in a considerable measure upon the factors giving rise thereto. It ranges from 4 weeks to 3 months. The attacks are most frequent in the earlier period and abate gradually, the paroxysms becoming less frequent in the 24 hours, and of briefer duration, and finally ceasing altogether by the end of the fourth or sixth week, or before the end of the third month. Exceptionally, they may continue with unabated severity for full 3 months to disappear very quickly or to abate but gradually after that time.

The attacks come on at various intervals throughout the day until a certain hour of the evening, when the infant will fall asleep and remain tranquil for five to six hours. Later on he will be comparatively free all day until 6 or 7 o'clock in the evening, when he will begin with his cries and know no rest except at intervals of a few brief moments until 10 or 11 o'clock or even midnight.

In the very severest cases the attacks may come on with unwonted frequency throughout the days and nights of this colicky period, and many poor mothers will spend their nights or the greater parts thereof in measuring the length of the apartment, walking to and fro with baby in arm, in their endeavors to quiet it.

It is a common saying among wise old ladies that boys are more subject to colic than girls. There are no statistics upon the subject, but my personal observation is fully in accord with this. Moreover, it has even seemed to me that when girls were colicky the paroxysms were much less frequent, less severe, and of briefer duration than in male infants thus affected.

What is colic? Colic is an irregular peristalsis mainly of the small intestines, a contraction of the various muscular coats of the intestinal tract, accomplished with such violence that the nerve filaments distributed between them are unduly compressed and the sensation of pain aroused.

This peristalsis is not necessarily attended by fecal discharge.

It is said by some writers, and with special reference to "infantile colic," that distention of the intestines by gases may cause the pain. It is true that an extraordinary distention of the bowel may give rise to pain, but it is not the pain of colic. Flatulence can excite colic only when there is no extraordinary distention of the intestinal tract and the gases shift about from one loop to another, from one section to another, from one side of the transverse colon to another, from left to right or right to left, exciting here and there this irregular peristalsis.

Colicky pains are part of the natural history of many very grave diseases of the intestinal tract, of inflam-

matory and ulcerative processes therein, of various congenital malformations thereof, and of various affections of the peritoneum, but colic considered as an entity is merely a functional disturbance with no underlying pathological substratum, and when the paroxysm is over, the normal equilibrium is quickly restored.

This is, no doubt, the explanation for the fact which otherwise would be inexplicable, that despite the great and frequently rather long-continued suffering of the infants afflicted with "infantile colic," they thrive nevertheless, gain in flesh and strength and progress as well as other children more favored in this regard.

The causes of infantile colic and colic in infants are:

1. Flatulence.
2. Sundry influences acting through the mother.
3. Indigestion.
4. Refrigeration.

I.—FLATULENCE.

Of all the etiological factors, this is the most important, giving rise to the most cases and to the most protracted ones. In fact, it is the etiological factor of "infantile colic."

As is well known, in the course of the digestive act, various gases are developed in the stomach and bowels in the process of the splitting up of the food and its transformation into assimilable material. Under ordinary physiological conditions the gases are but small in quantity, move slowly along downward with the chymus, and are finally discharged either alone or with the feces, without having caused the least disturbance.

In these colicky infants, however, the gases are either developed in undue quantity or are retained unduly long, and thus allowed to accumulate and then excite this exaggerated peristalsis as an effort of nature to dislodge them.

The reasons for this flatulent condition of the infant may lie in the infant or they may lie in the mother.

A. They may lie in the infant.

Up to the time of its birth, the infant was nourished through the blood of the mother and its digestive organs lay dormant. Now, suddenly and without any especial preparation, they are called upon to act their part in a very complex chemical operation. It is not far fetched to assume—we not infrequently see it in other organs—that the intestinal tract here has not reached the degree of normal efficiency. Though the colostrum of the first two or three days might be looked upon in the light of such preparation, it has evidently not been sufficient in the cases under consideration. The digestive act is not accomplished with the speed and perfection of a later period, and as a consequence, an undue volume of gas is developed.

Again, it is a well-known fact that the pancreas is a most important factor in the proper preparation of the chymus, as it comes from the stomach, into assimilable material. This organ, however, does not attain its full power till a much later period, in part not until nearly the end of the first year. It is true that Zweifel found that an extract of the pancreas of the first month from strong children was capable of digesting albumen, and the inference would be perfectly proper that the secretion of the organ, as poured out into the duodenum, should possess similar power. Still, even admitting this, it is at a much later period than the setting in of the colic, the second or third day.

This alone, in fact, would tend to prove the correctness of the position here taken.

Or it may be that for some reason the organ does not furnish sufficient secretion or a secretion sufficiently rich in albumen-splitting and oil-emulsifying ferments to complete the digestive process with the rapidity of a later period, and hence an abundance of flatus as a result of slower chemical operation.

It must be admitted that all this is hypothetical, as we very frequently find nothing in the stools, having reference now to the case of infantile colic more particularly, to indicate an imperfect digestion, and even when such indications are found they can, in the majority of instances, be readily accounted for by extraneous incidents.

It is, nevertheless, well to bear this explanation in mind, as it is based on physiological data and the clinical fact that slowness of digestion tends to the development of much flatus, and accounts for the cases, not so very many in number, it is true, where no extraneous factors or supposed factors can be discovered, and which would otherwise, therefore, be inexplicable.

It is of some moment in the consideration of certain cases of hand-fed infants as will be recalled further on.

B. They may lie in the mother.

1. *The Mother is Constipated.*—If the mother be constipated, the infant also is usually constipated or at least costive. This allows of the accumulation of flatus.

Again, all constipated persons are more or less flatulent, and the milk of a constipated mother is also of a more or less flatulent character and the flatulence will develop in the infant.

2. *The Diet of the Mother may be at Fault.*—The consumption by her of such articles of food as are known to be of flatulent character, as cabbage, cauliflower, peas, beans, etc., will make the milk flatulent, and the infant nursed therewith will become flatulent in turn.

II.—SUNDRY INFLUENCES ACTING THROUGH THE MOTHER.

1. *Purgatives.*—Cathartic remedies taken by the nursing mother affect the infant in a greater or lesser measure. This is well established. I have myself noted several instances where a dose of salts taken by the mother produced watery evacuations in the infant, even when the mother was not at all moved thereby. As is the nature of cathartics, they may excite colic. I have seen a number of cases where the administration of some form of senna, in decoction (as in *Infus. laxativ. Vienens*) or in extract (in pill with other ingredients) was followed by a very colicky state of the infant, though the mother was not in the least inconvenienced thereby. I have seen the same thing follow upon aloes and aloin.

The habit of taking purgatives at regular periods by constipated mothers, is frequently attended with much suffering for the infant—colics.

2. The eating of sour pickles or other articles prepared freely with vinegar, of raw fruit, the drinking freely of lemonade by the nursing mother, is usually attended with colics in the infant.

3. *Much Worry, and Anxious State of Mind on the Part of the Mother.*—There is no question now as to the influence of the mind upon the body, its functions and secretions; and the lacteal secretion is no exception thereto. This has been well recognized, and much stress is laid upon this point, the mental temperament, in the matter of the selection of a wet nurse when the necessity therefor arises. Sir Astley Cooper, in his work on the Breast, says, and the statement is repeated by Carpenter in his *Physiology*, that anxiety of mind of the mother may be

the cause of griping or tormina in the infant. I have had occasion to make the same observation. In one particularly striking case, no other possible cause for the severe colic of the infant could be discovered than this great mental worry of the mother, and with its disappearance, which occurred a short time later, the troubles of the infant at once ceased.

Fretfulness on the part of the nursing mother may be the cause of a colicky state of the infant.

Fits of Anger, Sudden Fear.—The milk nursed soon after such will most usually excite an attack of colic in the infant. Even more untoward and graver accidents have been known to follow the first of these two.

4. *Paroxysms of Pain Afflicting the Mother.*—Dewees, one of the great physicians of this country, and a most careful observer, relates a case of colic of 5 months' duration, due to such a cause. The infant was a stout child and in good condition for the first two weeks; then colics set in and occasional vomiting. He attended the child, and despite all he did or could do, it remained colicky; and not alone that, but it wasted away. It was about the end of the fifth month when he noticed accidentally one day at one of his visits, that the mother put her hand to her cheek and pressed it forcibly. On inquiry as to the meaning of the motion, he learned "that she was very much tormented, both by day and night, with the toothache, and had been so for some time before the child was born, and ever since." He declared this to be the cause of the child's sufferings, and directed that a dentist be sent for at once. This was done and the tooth extracted, whereupon the infant was quickly relieved of its colic and began at once to thrive again.

This is certainly well worth remembering, as very many women suffer with their teeth during pregnancy and continue to suffer after delivery for 3 or 4 weeks or even longer, until they are able to go out and consult a dentist. I have myself known in my clientele quite a number of ladies who dated the decay of their teeth from their first pregnancy.

As to the mode of action of these various factors relating to the mother and here mentioned, it suffices to say here, as has already been indicated above, that they act through the milk, and thus affect the infant. As to the details, these can be found in the various works relating to the nursing or feeding of the infant.

III.—INDIGESTION.

Indigestion may be the result of overfeeding or of the administration of improper food.

1. *Overfeeding.* *The infant is nursed too frequently.*—This is one of the most grievous sins of commission on the part of the mother against the well-being of the child. Many, very many, mothers believe that every time the infant utters a cry, it is hungry and must be fed, without any regard to the time that may have elapsed since the previous nursing or feeding. I have, in my long experience, found that the greater number of children were nursed or given the bottle as often as every hour, or even at shorter intervals, and at periods when they were fretful were put to the breast as often as every half hour.

There is no question in my mind, and I have called attention to it elsewhere,¹ that nine-tenths of the troubles of the digestive tract of infants, are due to overfeeding.

¹In various articles, but more particularly in "A Case of Indigestion in an Adult and Child," with Especial Reference to the Treatment of the Most Successful Treatment by the Mechanical Measures. New York, 1897.

and though it is true that but very little is said about this by writers, not at all commensurate with its importance, it is because mothers, and particularly nurses, are given to deception on this point; and unless you cross-examine very closely and sharply, you will not, in most cases, learn the truth. The mother, and most certainly the nurse, will not usually admit that the infant is ill through her fault.

In consequence of this overfeeding, an undue amount of food is introduced into the economy, much more than can be assimilated. It is a wise provision of nature that the great majority of infants regurgitate and spit out the excess of food that may have been taken during nursing, and therein the old saw is right that a spitting child always thrives.² In overfeeding, however, spitting out alone cannot accomplish much, and nature in its endeavors to guard the precious homunculus from harm, seeks to get rid of the superfluous aliment in a more effective way, through the bowels. As a result of this effort, we have exaggerated peristalsis,—*colic*.

There is also, as would be readily supposed, much flatulence present in these cases.

When continued for any length of time a dyspepsia is developed, especially in bottle-fed children, and this will tend to aggravate the paroxysms of colic, make them more severe and more protracted.

The infant is overfed in quantity, that is, too large an amount in proportion to the age, is given at one time, though the proper length of interval between feedings is observed.

This applies only to hand-fed children.

One of the severest and most intractable cases of colic observed by me was in an infant who received a properly prepared milk from an establishment making a specialty of furnishing milk for infants, but to whom at the direction of a medical attendant, the inordinate quantity of three times the amount proper to its age was administered at every feeding, though the intervals between these were perfectly correct.

It is supposed by many physicians that overfeeding always leads to diarrhea. This is not the case. As I have pointed out elsewhere,³ it is most frequently productive of constipation, especially in more vigorous children and in the cooler months.

2. *The Food May Not Be of the Proper Character*.—Occasionally the milk of the mother's breasts may be of an abnormal character; it is too acid; it is too salty, etc. It naturally disagrees with the child and causes it colic, diarrhea, etc.

Mainly, however, this applies to artificial feeding. The milk (and milk is really the best food for the very young infants) may not be of a healthy character. It may be acid; it may be sour; it may contain unhealthy and irritating elements. Again, though the milk itself be perfectly normal, it may not be properly prepared, not in accord with the digestive capacity of the infant.

In isolated instances, milk, no matter whence derived or how carefully prepared, may not be tolerated. Trousseau⁴ records a very striking instance of this. The children of a shipbuilder of Havre could not tolerate milk of any kind for the first seven years of their life. No matter whether it came from the human breast (mother, wet-nurses) or was taken from different animals, cows, goat and even the ass, the same effect was

always produced: diarrhea and vomiting. They were fed upon decoctions of grits and pearl-barley and thrived.

Much the same applies to other infant foods made from grain. For one reason or the other, they may disagree with the infant, and thus give rise to attacks of colics.

In older infants—infants who already eat—improper articles of food are a most frequent cause of colic. This is particularly so among the middle and poorer classes, where the infant of 10 months and over is set to the table at mealtime with the adults and usually given a bit of something to keep it quiet. I have not infrequently seen, among the more ignorant, a father, a mother, take the greatest delight in seeing their infant suck a piece of sausage, a bit of fried steak, and if the infant was old enough to bite off little bits and munch them, so much the better. To them it was a most wonderful performance.

It is well to bear this in mind, as when trouble follows and inquiry is made by the physician all such indiscretion on the part of the mother is denied in toto.

Sometimes, though not very frequently, it may happen that the colicky state is due to *underfeeding*. As can be readily understood, this applies only to nurslings. For one reason or another, usually from dire poverty, very rarely on account of defective conformation, the breast does not supply the infant with sufficient nourishment. The child is always hungry, crying, and making suckling motions. Reflexly the empty suckling at the breast, and away from it, will excite a gastrointestinal peristalsis, and as there is nothing or very little to contract upon, it soon becomes irregular, and griping results.

IV.—REFRIGERATION.

This may result in various ways. The infant is allowed to lay too long in the wetted diaper. Its abdomen is exposed to the cold air. Its food, if it be hand-fed, is given too cold.

In older infants, sitting on a wet floor, walking barefoot over a wet or cold floor, or drinking water that is too cold, may excite an attack of colic.

We find the same factors producing the same effects in adults. I have known of instances in adults where a sudden exposure of the abdomen to the cold air, as when the covers were accidentally thrown off during the night, was at once followed by an attack of colic. Walking barefoot across a cold floor is not an infrequent cause of colic in persons not accustomed thereto.

No further proof for this etiological factor is necessary. Indeed, upon this stimulant action of cold upon the intestines are based the various hydrotherapeutic procedures employed in the treatment of constipation.⁵

Other Factors.—1. Another factor assigned prominence by some authors in the etiology of colic is the swallowing of air. It is supposed to be of great influence in the production of flatulence. I myself lay no stress upon it. I do not believe that any infant sucks in enough atmospheric air to cause colic. I have seen, time and again, infants lie for hours with the short rubber nipple in the mouth, sucking away, at longer or shorter intervals, with great vigor, and this as a steady practice, and I cannot recall an instance where colic or a colicky condition resulted in consequence thereof.

2. Dewees thought that in a few of his cases of infantile colic, a malarial influence was the exciting cause.

² Speikinder—Gedemkinder.

³ See my book "Constipation in Adults, Children, etc."

⁴ Trousseau Clinical Lectures, Philadelphia Edition, vol. 2.

⁵ See my book, "Constipation in Adults and Children," etc.

There was a distinct periodicity about the attacks, and bark effected a cure.

It is worthy of note for those practising in malarial regions.

Symptoms.—1. The infant sleeping quietly in its little bed becomes restless all at once. It twists and moves about, now the arms, now the legs being in motion. The little forehead wrinkles, the angles of the mouth are drawn down, and a few short cries are emitted. These become longer, louder and more forcible, until at the height of the paroxysm the baby veritably screams and continues to do so until a relaxation sets in, which is very frequently, in infantile colic always, coincident with a more or less large discharge of flatus through the anus. It then becomes quiet again, the face resumes its former serenity, and baby is very soon asleep again.

Or it may happen in this wise: The infant has nursed and lies quietly and contentedly in the mother's or nurse's arms with eyes wide open or in a gentle slumber. Suddenly, after a more or less brief period after the feeding, the little one becomes restless. It twists and moves, now the arms, now the legs being in motion. The little forehead wrinkles, the angles of the mouth are drawn down and a grunt or two or a few short cries are emitted. These become longer, louder and more forcible as the pain increases, until at the height of the paroxysm the baby veritably screams and continues to do so until a relaxation sets in, which is coincident with several eructations of gas, which may or may not be followed by a free discharge of flatus. It then becomes quiet again; the face resumes its former placidity; even a smile, if the infant be old enough, may play upon its features and in a very little while it is soundly asleep.

When the attack is but slight, merely a twinge, only the first half of the phenomena will be observed—the restlessness, the movements of the extremities, the wrinkling of the forehead, the drawing down of the angles of the mouth—or even still more, the grunt or short cry. Then just as suddenly a relaxation sets in, a discharge of flatus, an eructation of gas has occurred, and the calm at once returns. The features again become placid, even smiling.

In older infants, the onset may be thus: The baby, soundly asleep, suddenly utters a loud and piercing scream and awakes. Or it may be sitting in its crib or on the floor, playing and cooing, and suddenly it screams out.

If it be but a passing twinge, the cry is rather short and not so loud, and all is past in a moment; the child is again sound asleep, having been hardly awakened, or it is again playing and cooing and smiling as before.

The face of the infant is congested during the crying spell; occasionally, and more particularly in older infants and children, the pain may be so severe that they cannot cry out and then the face is pale and the lips are blue.

This particular play of features, now quiet and serene, placid and smiling, in the next moment wrinkled, drawn and expressive of suffering, crying, and in a very short time again serene, again smiling, has been likened not inaptly, by a—to me—now unknown but evidently rather poetically inclined practitioner, to the phenomena observed in nature in the sweet spring days; the brightly shining sun, all nature smiling; then suddenly a gathering of the clouds, a darkening of the horizon, a brief rain and again the sun shining brightly, and all nature again smiling.

2. The hands and feet become cold with the onset of

the seizure, and continue so the whole duration of the paroxysm, but quickly resume their normal warmth when the attack has passed.

3. Another and very distinctive feature of simple colic is the movement of the legs; it is not, as usually described, a mere kicking, but the leg is flexed upon the thigh and the thigh upon the abdomen—all this with a rapid, upward motion, and then the whole limb is let go again and extended with an equally rapid movement, and then the procedure repeated *de novo*. This movement, made instinctively, is therefore not the mere kicking of a petulant child, but a movement wherewith to obtain relief, to make pressure upon the abdomen—just what we see done in the adult when similarly afflicted. Thus the adult, when seized with colic, will bend double, if he be standing up, or sitting; but if he be lying down, he will draw up his legs, flex them upon the thighs and these upon the abdomen, and thus make pressure upon his bowels and obtain easement. That this view is correct is demonstrated by this, that if the infant can make pressure upon its abdomen otherwise, it will not kick its legs. Thus, if at the onset of a seizure, or during a mild seizure, or while it is having colicky twinges, as shortly after feeding, the infant be held up in arms with its head upon the shoulders of mother or nurse, it will press its little belly firmly against the mother's or nurse's chest, as these will tell you, and thus ease itself; for it will be quiet and apparently comfortable, and as long as it is thus held, there will be no kicking.

4. The belly is usually hard during the paroxysm—a condition due to the contraction of the abdominal muscles. As soon as the attack is over, the belly is again soft, normal to the touch. There may be some fullness about it, particularly if there be much flatus present, or if the infant be constipated.

5. Constipation or costiveness may or may not be present. I have seen cases of infantile colic in infants, who had regular and normal movements.

There is usually no fever, especially so in infantile colic. In the cases due to overfeeding, more particularly in hand-fed infants, or to improper food, there may be occasionally some elevation of temperature, but it is generally only trivial.

In very severe cases the fontanels may be depressed.

Diagnosis.—The symptoms above related are so characteristic and stand forth so prominently, that the diagnosis of an attack of colic is readily and unerringly made.

That it is a simple colic will also be recognized by the very presence of these phenomena. In the attacks of colic supervening in the course of diseases of the intestines or the peritoneum, there is no such play of the features as described above. In these ailments, more or less grave, and always painful, the countenance of the infant bears continuously an expression of suffering that does not leave it until convalescence is fully established. During the colicky seizures, this is intensified, and when it is over, the face is only as before expressive of suffering, not the again calm and serene countenance of the otherwise healthy child.

I attach great importance to this play of the features, so much so that almost upon this alone I made the diagnosis of simple colic in a case to which I was called in consultation with an excellent colleague, who was inclined to regard it as one of intussusception.

The infant, about 17 months old and well nourished, had been taken out by its mother one afternoon on a

visit with her to some relatives, and these in their mistaken kindness had stuffed it with cake, milk, etc. When it again reached home at a late hour that evening, it was restless, and at intervals would cry out loudly as if in pain. Early the next morning a physician was called who, having learned that contrary to its usual habit the child had had no movement since the previous morning, prescribed an enema and some simple remedy. No movement resulted. After a while a little colored fluid passed from the bowels, and there were some drops of blood on the diaper. It continued to cry out at intervals, as before.

I saw the child about 1 P.M. It was in its mother's arms, and was then sleeping quietly with unruffled countenance. I examined the abdomen and found it full, but fairly soft. I could detect nothing abnormal about it on deep palpation. There was some slight elevation of temperature, but it was trivial. As I watched the infant as it thus lay with eyes closed, evidently sleeping, I noticed that all at once its face would become drawn, it would twist about somewhat, make some slight movement with its legs and then in another moment it was all past, and the face was again as placid as before. Occasionally, when the twinge was over, a smile would illumine its countenance. Upon this special feature I made the diagnosis of simple colic, advised the appropriate treatment, and in a short time, as I was subsequently informed, the infant was permanently relieved.

Again, in the colics coming on in the course of the grave pathological conditions referred to, there is no kicking of the legs. Such forcible movements would only aggravate the suffering already endured, and instinctively, therefore, the infant holds its lower extremities motionless, either fully extended or but slightly bent at the knee.

Lastly, there is here always an elevation of temperature of a more or less marked degree.

The contrast between these two forms of colic is thus very marked.

In the youngest infant, 2 to 4 days old, the question must arise as to any congenital malformation of the intestinal tract, as absence of anus, of anus and rectum, etc., etc.⁶ This we can readily decide by the inquiry: Has the infant had the usual fecal movements? If it has had the usual passages then any such etiology is of course at once excluded; if it has not had any movement, or if it has had but one movement, then we must examine and discover for ourselves the reason for their absence.

As to the recognition of the individual etiological factors of simple colic above recited, that is here, as in other maladies, a matter of careful inquiry and examination.

This much only need be said in addition. The presence of an undue volume of flatus can be determined by the rumbling and rolling heard in the infant's bowels as we stand by its crib or as we hold it up in our arms against us; or we may detect its movements in the intestines with the hand laid lightly upon the little abdomen.

Overfeeding, or indigestion, may be indicated to us by the stool. When these are the causes of the trouble, the stool will contain an unusually large amount of cheesy matter readily distinguished, sometimes so much that the stool may be almost nothing else but curds and perfectly white in color.

When foods of the cereal group are used they may be found in the stool in readily recognizable form.

If we suspect that improper food has been given the infant, a macroscopic or microscopic examination of the feces may give us certainty.

Underfeeding.—An almost constant crying, the cry rising at times to a scream, with which, at periods, no kicking of the legs is observed, a rather hungry appearance of the face, and a very insufficient gain in weight or even absolute loss therein, should at once direct our attention to this etiologic factor. An examination of the breast and an inquiry as to its secreting capacity, will soon disclose to us the true state of affairs.

In obstinate constipation we may find the stool in the form of hard, dry scybala, and not infrequently these are partly colored.

If the infant is costive we will learn on inquiry that it does not have a sufficient number of movements, or even when it does have these, that it squeezes until its little face is almost livid, and this even when the dejections are fairly soft.

That it is colic and not hunger that makes the infant cry, we will know by the fact that in hunger there is no *kicking of the legs, no screaming*; moreover, the hungry infant can be pacified for a moment, by a change of position, by taking it up; the infant suffering from an attack of colic cannot and will not be pacified until the spasm is over.

Treatment.—The treatment of infantile colic and of colic in infants divides itself naturally, as shown by the exposition made here, into two parts:

- (a) The immediate relief of the infant.
- (b) The removal of the exciting cause.

I.—THE IMMEDIATE RELIEF OF THE INFANT.

From time immemorial, the aromatics or carminatives have been employed in the treatment of this affection, and whilst at the present day they still suffice for many, others have recourse to more potent drugs, the antispasmodics, and others again to still more powerful agents as the opiates, chloral, hydrocyanic acid, etc., giving them either alone or in combination with some aromatic or antispasmodic. Even laxatives in very minute doses have found favor with some. The alkalies are sometimes prescribed with the view, it is said, of neutralizing a supposed unnatural acidity of the stools, but a scanning of the various formula will suffice to show that the small doses ordered cannot accomplish much, if anything, in that direction. I believe it to be more a traditional practice, which it is sought to place upon a rational basis.

The alcoholic stimulants, which in the very small doses are really aromatics, have long been, and still are, the remedy of the housewives and of the grandmothers.

The favorite prescription of one of the more ancient coryphees of medicine of this country, Dewees, was the following:

R.—Magnesia alba. usta. 1 scruple.
Tinct. foetid.* 60 drops.
Tinct. thebaic.† 20 drops.
Aq. font. 1 ounce.

Of this 20 drops are given, and if the infant is not relieved in half an hour, then 10 more are administered. "This dose is calculated for a child from 2 weeks to a month old. If it be older, a few more drops must be

⁶ See Bodenhamer, "The Congenital Malformations of the Rectum and Anus." Illoway, "Constipation in Adults and Children," etc.

*Tinct. Asafoetid.
†Tinct. Opin.

given; and as the child advances in age or becomes accustomed to its use, the proportions of the ingredients must be a little increased.¹⁷

Starr, the eminent pediatricist of the City of Brotherly Love, makes a prescription as follows:

R.—Sod. bicarbonat 16 grains.
Syrup $\frac{1}{2}$ fluidounce.
Ag. menth. pip., enough to make 2 fluidounces.
M. Sig.—One teaspoonful p.r.n. for a child of one month.

This prescription, he says, can be made more efficient by the addition of 2 drops of aromatic spirits of ammonia to each dose, or in severe cases, 1 drop of spirit of chloroform.

He has found good results follow the administration of 10 drops of gin in a teaspoonful of sweetened warm water.

Bromid of potassium and chloral he thinks most useful for the severe cases. This formula is the following:

R.—Potass. bromid. 16 grains.
Chloral hydrat. 8 grains.
Syrup $\frac{1}{2}$ fluidounce.
Ag. menth. pip., enough to make 2 ounces.
M. Sig.—One teaspoonful for a dose. Can be repeated if necessary 2 to 3 times at intervals of half an hour.

John Thompson, of Edinburgh, believes that the best immediate treatment of an attack of colic consists of irrigating the lower bowel with a large quantity of warm water or administering a copious warm enema. The application of hot fomentations to the abdomen and of warmth to the feet are also serviceable, and 20 drops of whisky or a dose of carminative may help to relieve the child. An aperient is usually indicated to clear away irritating matter, and if the bowels are habitually constipated, this should be attended to. When there is obstinate recurring colic, small doses of codein ($\frac{1}{32}$ to $\frac{1}{16}$ of a grain) are occasionally useful as a temporary palliative while the diet is being gradually regulated.⁸

Vogel teaches that the treatment of an attack of colic consists in the cautious employment of narcotics, particularly the preparations of opium, of hydrocyanic acid and nux vomica, or in ethereal, aromatic remedies, chamomile, peppermint or melissa teas applied per os or per anum.⁹

As already said, the home treatment of the mothers and grandames consists in the administration of some alcoholic liquor, as whisky or brandy or gin, or of a decoction of some aromatic herb, as peppermint, chamomile or catnip, or of seeds as fennel—the tea from the latter being particularly favored by German mothers.

In the earlier days of my practice, when crying infants were a sore trial, I also prescribed the opiates, making use of the various preparations, now of the camphorated tincture, paregoric, then of a certain supposedly denarcotized preparation of opium¹⁰ and again of the simple tincture, usually ordering them in combination with aromatic syrups of rhubarb or syrup of ginger and some aromatic water.

Infants become readily accustomed to opium and soon require larger and larger doses of it, and therefore, in protracted cases, I preferred to avail myself of other medicaments. I now remember very well a most

intractable case of infantile colic, in which all home remedies had been tried without benefit, for which I prescribed 3 drops of laudanum with 5 drops of whisky, to be given in two doses. At first, the one dose sufficed, then after a few days it required both doses to quiet the infant, and still a few days later even the two did not suffice and my juvenile friend kept up his shrieks as before. He would not be laid down on his bed at all, and the only way a moment's peace was gained was by holding him in arms and walking the floor with him.

Being afraid to increase the dose of opium beyond what had been already reached, I resorted to chloral hydrate and gave a prescription which I continued to use subsequently, and which I have always found effective where a soothing or hypnotic effect was desired. It reads thus:

R.—Chloral hydrate 6 to 10 grains.
Mucil. G. acac. 1 dram.
Lac. asafetid. 2 drams.
Essent. anisi $\frac{1}{2}$ dram.
Aq. fenicul. 3 drams.
Sirup rhei. aromat. $1\frac{1}{2}$ dram.

M. ft. mixture. Sig.—One teaspoonful for a dose. To be repeated in 30 minutes, if necessary. For an infant from 2 to 6 weeks old. For older infants, the dose of chloral can be increased (to about $1\frac{1}{2}$ grains).

With larger experience I found that a more systematic treatment was required for a condition produced by dissimilar causes, than the mere routine prescribing the same formula in every case.

I also found that certain simple remedies acted as efficiently and as quickly, yes—even more so than the more powerful narcotics and hypnotics, and that, therefore, these could be dispensed with in most instances, a matter of certainly much moment to the infant, and of great advantage to it, as I consider.

In infantile colic, I have found nothing superior to the milk of asafetida. Made from the fresh gum, as directed in my book on Constipation, it brings relief in a very brief period after its administration. It is given, and in a few minutes thereafter, there begins a cannonading on the part of the infant, a discharge of flatus, that would do credit to a diet of beans; or eructations ensue. The cries cease, the frowns pass, and the child is again quiet, serene, smiles.

I direct that $\frac{1}{2}$ to $\frac{1}{4}$ teaspoonful be given, followed, if necessary (but this very rarely happens), in 15 to 20 minutes by a second dose, to the youngest infant. A little fine sugar is placed upon the tip of the spoon (if preferred a drop or two of the syr. rhei. aromat. can be put there) and the spoon then placed to the infant's lips and the medicine allowed to flow in.

Infants, 95 out of every 100, take it readily, even like it, and there is, therefore, no struggling.

Occasionally, I make use of the following formula:

R.—Lac. asafetid. $\frac{1}{2}$ ounce.
Sirup manna $2\frac{1}{2}$ drams.
Essent. anisi $\frac{1}{2}$ dram.
Sirup rhei. aromat. 1 dram.

M. Sig.—One teaspoonful for a dose.

The remedy is innocuous, and can, therefore, be placed with perfect safety in the hands of the mother or nurse, and its administration fully intrusted to them—a matter certainly of much moment for its future welfare, to the infant thus afflicted, often requiring, especially at the outset, 2 or 3 more doses per day, and that for a long period perhaps, of a medicine that shall be effective.

¹⁷ Dewees; *loc. cit.* at end of Article.

⁸ Clinical Treatment of Children, PHILADELPHIA MEDICAL JOURNAL, October 28, 1899.

⁹ Melissa calamintha smells like wild mint. It is used popularly as a tea in dyspepsia, in flatulent colic.

¹⁰ Which is said to be only about one-third the strength of the simple tincture and from which the convulsant elements, it is claimed, have been removed.

To show more clearly that I have not exaggerated as to the potent influence of asafetida on flatulent and spasmodic states of the intestine, the following case of an adult, in whom its use was attended with brilliant results, is here appended :

K. F., living in a large Western city, clerk, aged 22. An inveterate cigaret smoker, a great drinker of coffee and most liberal consumer of whisky. Since a number of years he had suffered from frequently recurring, violent attacks of pain in his bowels, which in the last year and a half have become so severe that hypodermic injections of morphia were often necessary to allay them. He was treated for dyspepsia, for liver trouble, and finally a condition of chronic inflammation of the intestine or a chronic appendicitis were suspected. He was badly run down, very much emaciated, and not able to do much. As he was in such bad shape and nothing seemed to benefit him at home, he was sent here to me. I examined him carefully, and found absolutely no pathological lesion of the intestinal tract. The other organs also appeared normal. I concluded that his pains were due to attacks of colic. I stopped his cigalets, his coffee, his alcoholic drinks, and put him on a diet. The fourth day after his arrival here, and whilst in my office, he had a most frightful seizure. He became pallid, hands and face cold, features pinched, pulse small; he couldn't speak; it looked like approaching dissolution. I laid him on the sofa and then sought for some remedies. I happened to have a few ounces of milk of asafetida in the office, and this being first at hand, I poured out a full ounce, added 20 drops of Hoffmann's anodyne and made him drink it. In 5 minutes thereafter he was up and declared he was feeling all right again; and in a further 5 minutes he left. He had no further attacks during the whole period of his stay here, and grew fat and stout. Returned home and again among his old companions he resumed his old habits, and after a time the seizures again appeared, but never as violently as before, since he always cut them short and quickly relieved himself with a liberal dose of the asafetida, which he has put up for himself by the quart, and which he is never without.

There can be no possible objection to the remedy, except, perhaps, its odor; but I have never yet had a sensible mother object to its use on that account, when its more than overbalancing advantages were fully set before her.

When the infant is inclined to spit much after its administration, indicating evidently that it does not relish the taste, a few teaspoonfuls of sweetened warm fennel tea will at once wash away all the residue that may have remained in the mouth, both of medicine and odor.

I was informed by some very observant mothers, that a few teaspoonfuls of warm fennel tea increased the rapidity of action of the asafetida, and that with both the infant was relieved in a marvelously brief period.

When the attack comes on shortly after nursing (and this may occur even though we can detect nothing abnormal in the milk) we can frequently prevent it by giving the infant shortly before or very soon after nursing, a dose of the medicine. In older infants, 4 or 5 weeks, we can sometimes obtain the same result by preceding the nursing 15 or 20 minutes with an ounce of warm, sweetened fennel tea, administered by means of the nursing bottle.

In very mild seizures, twinges only as it were, sweetened warm fennel tea, a few teaspoonfuls for the very young infants, an ounce or two, according to age, for the older ones, may quickly arrest the griping and thus give relief.

If the infant be inclined to be costive, an enema of warm water with a little sweet oil added thereto, or a soap suppository, may be directed as occasion may re-

quire, in addition to the medicine to be given internally.

In the colic due to overfeeding, to indigestion, to constipation, to improper food, I have found that the suffering was quickly relieved by a mixture made as follows :

R.—Mist. rhei. et sod $\frac{1}{2}$ ounce.
Hoffmann's anodyne 40 drops.
Syr rhei. aromat. enough to make 1 ounce.

M. Sig.—Dose, $\frac{1}{2}$ teaspoonful repeated in $\frac{1}{2}$ to $\frac{3}{4}$ of an hour for an infant 3 to 4 weeks old. For younger infants the dose is 15 to 20 drops; for older ones from $\frac{1}{2}$ to 1 teaspoonful, according to age.

Usually 2, at most 3, doses are all that are required.

If there be much overloading of the bowels, an enema, as described, or a soap suppository, in addition to the above, will be of much benefit.

If the colic be due to refrigeration, we will direct the application to the abdomen of dry heat, as a couple of layers of flannel, well warmed, or a tin plate heated and sufficiently covered with cloths, so as not to burn; we will have the feet wrapped in a warm cloth and we will order that the child be given a warm sweetened decoction of peppermint or fennel seed (infants generally seem to prefer the latter). By these measures we will quickly chase the furrows from the brow of our little patient and bring back his cherubim smile. He will once more be comfortable.

Sometimes the administration of a little good whisky, brandy, or gin—10, 15, 20 drops (according to age) in a little sweetened warm water—will accomplish the same purpose and will bring quick relief.

Or the milk of asafetida with some aromatic, as in the formula above given, may be directed, and it will be found of great benefit. It is always to be preferred to the alcoholic stimulants with infants inclined to be nervous, or having a tendency to convulsive movements. Occasionally, in infants with a peculiarly sensitive intestinal tract, an opiate may be required, and here the camphorated tincture of opium, the paragoric of the Pharmacopeia answers best, I believe.

R.—Tinct. opii. camphorat 1 fluidounce.
Aq. menth. pip 5 to 5 $\frac{1}{2}$ fluidounces.
Syr. rhei. aromat. 1 to 1 $\frac{1}{2}$ fluidounces.

M. Sig.—Dose, $\frac{1}{2}$ teaspoonful repeated in $\frac{1}{2}$ hour if necessary. A further dose can be given in 2 hours.

It is only when this condition unquestionably exists that the administration of a preparation of opium in a case of simple colic (in an infant) is at all necessary or justified.

II.—THE REMOVAL OF THE CAUSE, *i. e.*, THE PROPHY-LACTIC TREATMENT.

1. Where the cause lies in the infant, as has been already set forth under heading I, A, there is really nothing more to be done than has already been there said, and to bide the time. Starr believes that the routine administration through the whole colicky period of a little wine of pepsin (15 drops three times a day) is beneficial, and I have occasionally prescribed the elixir of lactopeptin, to be taken 3 times daily between meals, as an agreeable aromatic preparation, very readily taken by infants and children, and I believe I have derived benefit therefrom.

Thompson advises Papain. He makes a prescription thus:

R.—Sod. bicarbonat..... 3 gr ins.
Papain (Finkler) 1 grain.
M. ft. pulv. I. Sig.—One after each meal.

Sometimes he directs the following mixture :

R.—Sod. bicarbon. 3 grains.
Spirits ammon. aromat. 1 minim.
Spirits chloroform. 1 minim.
Syrup.....10 minims.
Dill. water sufficient to make..... 1 dram.
M. After each meal.

I do not favor the administration of an alkali, that is as routine treatment, and certainly not at all immediately or shortly after meals; it cannot but help to impair a digestion already innately weak, perhaps even cause an acidity, and thus still further aggravate the evil.

2. When the infant is costive or constipated, we will have to regulate its bowels to the normal standard. Some indications, therefore, have been already given here, but the fuller details as to the rules and methods to be employed for this purpose can be found in my work, "Constipation in Adults and Children," etc.

3. If the mother be constipated, we will seek to effect a regular and normal evacuation. During the puerperium we will keep the bowels soluble by means of laxatives, enemas, glycerin suppositories, or glycerin injections, and by the aid of such articles of diet as are not contraindicated by the special period or by the condition of the infant (syrups, oatmeal, cracked wheat, etc.) All cathartics, especially those that gripe, must be avoided, as they may act too energetically upon the infant. Later on, if a normal soluble condition of the bowels has not been attained by the measures already named, we will resort to the mechanical methods, the details of which can be found in my work just mentioned above.

4. If the troubles of the infant be due to a faulty diet of the mother, we must correct this. We will strike off from her dietary all such foods as are said to be flatulent and which have been already named above, and all such food preparations as are in themselves conducive to colic, as has already been set forth. Where the intestinal tract of the infant seems peculiarly sensitive, she may have to abstain from acid, raw fruits, such as apples, oranges, and sometimes even from some stewed fruits, as stewed apples. Where, however, this is not the case, these fruits in small quantity may be allowed and will be of great service.¹¹

The various other indications in matters that refer to the mother, these may be readily inferred from what has been said in the section on etiology and need no repetition here.

5. If the infant be overfed, either that it be nursed or fed too frequently, or that too much be given it at one time, we will insist on the observance of proper periods for nursing or feeding, or on the proper amount to be given at one time, and fully impress upon the mother the necessity of a strict observance of these rules, both for the future welfare of the infant and for her own comfort. The details can be found in the various treatises on diseases of children, and in my work already here named.

6. If the infant be underfed, we will have to do one of two things—either endeavor to secure, if possible, a more abundant supply from the breast, or make good the deficit by properly regulated hand-feeding in addition.

As to the proper character of the food, a most important matter as regards the welfare of the infant. Whilst many children thrive readily on the various artificial foods that may be given them, others again—the few, it is true—will not do well upon the most careful and scientific preparations. Here, all violation of the well-established rules of artificial feeding being excluded (and this is of the first importance, for, as said elsewhere, in the great majority of instances, where the artificial food disagrees with the infant, causes colic, etc., it is not really the food that is to blame, but the over-feeding), the question arises: Is it the food that is at fault, or is the digestive capacity of the infant insufficient, and would it have the same troubles even if it were nursed from the breast? The further details do not pertain here: they can be found in the various treatises on Diseases of Children, and in that very excellent book, "Routh on Infant Feeding." I would only add this, that when this question of a proper food presents itself, it is well to bear in mind the following points:

a. If the milk mixtures disagree with the infant, cause colic, etc., we may improve them and perhaps remove altogether the tendency to gripe by using as the diluent, an aromatic water, fennel or caraway water, as has been suggested by Starr.

b. If we find that milk disagrees absolutely, we may follow the lead of Trousseau, as indicated in the cases above related.

c. Or, where the various foods seem to disagree, we may adopt the advice of Vogel and accustom the infants as quickly as possible to meat broths, which with slight cereal additions make a very excellent and palatable food.

In all cases where, for one reason or another, the mothers had to give up nursing their infants at a later period, say after 7 months, I had recourse to feeding with meat broths with the juice of some cereal, as barley, rice or oatmeal, added thereto, eschewing milk altogether, especially if it were near the summer months, and always found that the children did well and thrived thereon.

As to other prophylactic measures they are pointed out by the etiological factors themselves.

Complications and Sequela.—It is stated by some writers that convulsions may supervene upon attack of colic.

That convulsions are sometimes caused by irritant substances in the intestinal canal I have not infrequently observed. It is possible, indeed it is more than likely, that these latter provoke such severely painful griping, as to throw the infant into a spasm, but a convulsion following upon a well-marked attack of colic I have never witnessed.

Hiccough is a most frequent sequel of the seizure in infantile colic, especially after seizures coming shortly after meals.

It can be quickly stopped by a few grains of fine sugar put into the infant's mouth by the mother's or nurse's fingers. A little water will sometimes answer the purpose.

THE DIAGNOSIS AND TREATMENT OF SOME FUNCTIONAL FORMS OF DEFECTIVE SPEECH.¹

By G. HUDSON MAKUEN, M.D.,

of Philadelphia.

TO THOSE not having given especial attention to the science of speech, the subject is involved in more or less mystery, and this is doubtless due to the fact that the early development of speech is instinctive, automatic, and imitative, rather than analytic. It is safe to say that all speech is defective when measured by strictly accurate and scientific laws; and it is only when some marked abnormality arises that our attention is called to it. We are satisfied generally with any form that may serve to express our thoughts, and have very little regard for its aesthetic character. We even grow accustomed to our faults of speech and learn to accept them in preference to the correct forms. Thus the ear is not always a safe guide in these matters and it becomes necessary to train the sense of hearing as well as the faculty of speech.

Schools have been established for the improvement of speech and much good has been accomplished in this direction; but the progress of the work has been greatly impeded by a lack of uniform and scientific standards. These schools have met the requirements of those having fairly good speech, but owing to their lack of a scientific basis, they have not reached that large class of unfortunates whose speech is partially or wholly unintelligible. It is to supplement, therefore, the work of the schools that I make a plea for the careful study of the physiology and pathology (if I may use that expression) of speech by physicians; and by no class of physicians can this work be so successfully accomplished as by the specialist in diseases of the throat and related organs. Defects of speech belong naturally to our specialty, and their careful study with a view to classification, diagnosis and treatment, should be encouraged in every possible way. I may add without fear of being misunderstood, that not all men engaged in throat work can be equally successful in meeting the difficulties that arise in this particular line of investigation. Just as the pathologist requires years of careful preparation for his work, so must the one engaged in the study of speech have acquired not only a thorough theoretical knowledge of the physiology of speech and voice, but also that practical knowledge of the use of the organs employed in speaking which comes from special training in vocalization and articulation. This practical knowledge is useful not only in making the diagnosis, but also in giving the prognosis and directing the treatment, just as in the treatment of any disease one must know what the trouble is, what the cause is, and to what extent the cause may be removed and the trouble corrected. He must learn to compare the defective speech with the normal speech, not in a general, but in a particular way. Each element of the defective must be compared separately with the corresponding element of the normal speech and a complete record kept of the comparison.

In following this plan a serious difficulty always arises from the fact that our English alphabet, in many instances, gives the names rather than the sounds of the letters used in the language. For instance, the letter b is composed of two elementary sounds,—b and ē; g is composed of three elementary sounds,—d, zh, and ē;

and the letter w is composed of six elementary sounds,—d, ū, b, l, y and ōō. Hence it is clear that we cannot compare the defective sounds in speech with the standard alphabet of the language, and we must therefore, construct an alphabet of sounds. This was done as early as 1827 by the British physicist, Dr. Neil Arnott; and his alphabet was modified during the last decade by Dr. John Wyllie, of Edinburgh, who very properly gives it the name of "The Physiological Alphabet." I have reproduced it here with some slight additions and refinements, and I shall endeavor to show its application in the treatment of the various forms of defects of speech. My revised physiological alphabet contains 44 sounds, which may be designated as follows:

THE PHYSIOLOGICAL ALPHABET.

CONSONANTS.				
	VOICELESS ORAL	VOICED ORAL	VOICED NASAL	
Labials	P Wh	B W	M	Paul Brown made white wax.
Labio-dentals . . .	F	V		Full voice.
Linguo-dentals . . .	Th'	Tb''		Think thou.
Anterior	S Sh	Z Zh		Some zealous sheep
Linguo-palatals . .	T	D L R	N	leisurely took down nine large rails
Posterior Linguo-palatals . .	K H	G Y	Ng	Can girls bring home yeast?

VOWELS.				COALESCENTS.			
ā	ā le	ō	ō ld	ar	f ar e	or	f or e
ā	ā t	ō	ō n	ar	f ar	or	f or (aw)
a	a lus	oo	oo ze	er	h er e	oor	p oor
a	a ll	oo	l oo k	er	h er	ūr	p ū r
ā	ā sk	ī	ī t				
ē	ē ve	ū	ū p				
ē	ē lk						

It is quite probable that not one person in a thousand gives these sounds as here represented, and hence it is that nearly all speech is defective. There is no perfection in speech, and the best of us only approximate the correct forms. With this alphabet, however, as a standard of perfection, we compare the speech of each individual patient and we make a record in which appears an exact account of every deviation from the normal. To those who have learned to read we give sentences containing all the elements in the alphabet, and every departure from the correct sounds of these elements we carefully note and record for future reference.

Having thus determined in what respects the speech of the patient differs from the normal, and having recorded it in the case book, we proceed to investigate the causes of the defect. These causes are as numerous as are the defects themselves, and they are not always easily discoverable. A word with reference to the general development of speech may throw some light upon the subject.

The three mechanisms employed in the early development of speech are the auditory, the vocal, and the oral mechanisms, and each one of these may be again divided into central and peripheral mechanisms. In

¹Read before the Laryngological Section of the New York Academy of Medicine, October 24, 1900.

the later development of volitional speech, the higher psychic centers are also employed. The child first uses the organs of speech in crying, and this generally begins, in the normal child, immediately upon his advent. This is not an expression of pain, but it is the result of a reflex action of the musculature of the peripheral respiratory and vocal mechanisms. It is entirely subcortical and it is the result of various external stimuli attendant upon the child's new environment. (That it is independent of the higher central mechanisms of speech is shown by the fact that a similar action takes place in both the deaf child and the idiot, and to such an extent is this true that it is impossible to diagnosticate deafness in a very young child, and it is very often difficult in the first year or two to distinguish between the child of normal and the child of abnormal brain.) It is quite possible, however, that the child soon begins to experience a pleasurable sensation in the use of these organs, which acts as a stimulus to the development of their volitional exercise; and, as I have shown elsewhere, the mere physical use of the organs of voice, independently of any intellectuality, continues to give pleasure throughout the life of the individual; and this explains physiologically the great delight that people often take in talking, as well as the origin of the development of speech.

After a longer or shorter period of crying, the child begins to utter other apparently meaningless sounds, and to echo short words or syllables which have been used in his presence. Then he gradually begins to associate certain sounds with persons and things. All this takes place before the child does much thinking on his own account. The pleasure that he derives from this crying, babbling, prattling, and almost unconscious mimicry of sounds now becomes a strong incentive to volitional effort,—and it is here that the trouble begins. When the budding intellect begins to assume control of the hitherto automatic speech processes, unless the entire machinery of speech is in perfect condition, there will be more or less friction which may result in either defective articulation or stammering, or, as is often the case, in both of these conditions.

All speech is acquired by imitation; and could normal children have perfect examples, the result would be the development of accurate speech; but all children are not normal and they have no perfect example or model—hence the development of all kinds of speech, from the wholly unintelligible to the proximately correct. The auditory center is closely related to the speech center, and their development is simultaneous. The great importance of the ear in the development of speech is well illustrated by the fact that deaf children do not acquire speech at all, except as the result of special training. In the young child the auditory center first receives the impressions of sound, and the speech center responds almost immediately by trying to reproduce these sounds. If, owing to a faulty condition or action of either the central or peripheral organs of speech or hearing, the reproduction happens to be inaccurate, the auditory center seems not to be able always to detect this inaccuracy, and it registers it as being accurate. The trouble may arise originally from some temporary derangement of the nervous organization or from some abnormal anatomic structure or pathologic condition of the peripheral organs of speech and hearing. As examples of abnormal structures, I would refer to hare-lip, cleft palate, and other forms of arrested development; and as examples of pathologic conditions, to the various catarrhal processes of the throat and middle ear.

Defects of speech may arise, therefore, from either subjective or objective causes. In the former class would be included all those that exist within the child's own organism; such as first, a defective hearing apparatus; second, a defective speech apparatus; and third, a defective psychic apparatus, especially those centers presiding over the intellect and will. In the latter class would be included all those causes which may arise from the child's environment; such as first, bad hygiene, affecting the general health; second, the atmosphere of excitement in which so many children live and by which their nervous organizations become impaired; and third, faulty examples of speech given children by those in attendance upon them, and the encouragement of the continuation of baby talk for the amusement of others.

No discussion of the treatment of defects of speech is satisfactory which does not deal with the question of prophylaxis. What measures may we adopt in the training of children to prevent the development of defective speech? This is an important question because of its great practical value. To direct the formation of good speech habits is often a simple procedure, but when habits of faulty speech are once formed, we have a more difficult task to perform. That this task, however, is not altogether hopeless has been shown by the results already obtained in this work. The proper early training of young children would undoubtedly prevent the development of defective speech in a large percentage of cases. The physical condition of the child has much to do with the development of all his faculties, and there is no faculty which reflects this condition so accurately as does the faculty of speech. Poor health, either inherited or acquired, is a common cause of defective speech; and if it exists during the first few years of the child's life, its effects are specially pronounced. Some of the most serious cases I have ever seen were the result solely of a marked asthenic condition due to anemia during the early formative speech-period. The general health, therefore, should be kept in the best possible condition.

In addition to this, in many children the demonstrative disposition, as evinced in the babbling and prattling of which I have spoken, should be encouraged, not in an excitable, but in a calm manner. These demonstrative tendencies in some healthy children may occasionally require mild repression, lest an overexuberance of spirits result in an incoordinate nerve and muscle action which manifests itself in stammering. It is quite possible that the majority of cases of this latter defect might never have stammered if their early training had been of the right sort. Baby talk, amusing and cute as it may be, should be encouraged only up to a certain point, and not beyond the period of babyhood. Examples of good speech should be given children, and the imitative faculty should be encouraged. It is interesting to note what interest young children often take in mimicry; and this tendency, often manifested early in life, should be taken advantage of in the development of speech.

An early examination of the organs of speech should be made in all cases in which the beginning of an arrested development is suspected. Hypertrophied tonsils, pharyngeal, faucial, and lingual, should receive early attention and all structural irregularities should be corrected, keeping in mind the fact that speech is greatly influenced by these conditions during the first few years of childhood.

The above prophylactic measures are useful in all

forms of defective speech, but they are especially applicable in that form known as stammering. Other forms of defective speech are due to arrested development, but stammering is an acquired defect. It is not congenital, nor is it inherited, although we have ample proofs of the fact that the nervous conditions predisposing children to this affliction are often transmitted through several generations. Those who acquire the habit of stammering as a result of these inherited tendencies are probably the most difficult to cure, for it is necessary, by systematic and persistent training, not only to break up the habit, but to actually work some indescribable changes in the anatomy and physiology of the nervous organization. The patient has inherited a nervous system that is at least functionally defective, and that is probably not altogether free from organic defects. The child, therefore, whose ancestors have stammered, and he who shows the slightest predisposition to this form of defective speech should be very carefully managed in order that the habit may not be established. He should be led unconsciously to think slowly and to speak slowly; he should be shielded from all excitement, and never permitted to try to describe exciting events. Great tact must be used in diverting his attention from the exciting subject to something of less interest, without acquainting him with the reason for it. This reason, however, he should never know because it would arouse the fear of stammering and a mental expectancy which militates very materially against future freedom of speech. The attention of the child should never be called to the defect, and the word stammering should never be used in his presence. This is a most important injunction; many children have been made confirmed stammerers by having had their attention called to the enormity of the offense, and by having thus acquired a nervous dread of the affliction.

I shall now endeavor to describe to you the plan of treatment that we have found to be most effective, taking up first, those cases in which defective articulation, due to arrested development, is most pronounced; and, second, that form of defective speech known as stammering which, as I have said, is an acquired form and which, I may add, generally manifests itself in a faulty coordination of the vocal with the oral mechanism. In the articulatory form of defects of speech, we first get an accurate record of the actual defects as they exist by comparing the faulty sounds given with the correct sounds as indicated in the physiologic alphabet; and each element of speech that is found to be defective is taken up separately and the patient is taught the physiology of that element. He is shown to what degree the mouth should be open, and what position the lips, tongue, and palate should take for its correct enunciation; a hand mirror being used to aid him in acquiring the correct positions. At the same time attention is given to correct breathing and vocalization. It is explained how the articulatory organs may be regarded as moulds into which voice is poured; and how much for each sound, a separate and distinct mould is required; and the size and shape of this mould, and the manner in which it is made are fully described and illustrated. The patient is instructed, while endeavoring to get these positions, to give the closest attention to the resultant sound, in order that he may as speedily as possible hear the correct and distinguish it from the faulty sound. This training of the auditory center of the brain is of the utmost importance. Just as a defective ear is an insuperable barrier to the acquirement of a practical

musical education, so is an ear that fails to distinguish between the faulty and correct sounds of speech a great hindrance to the development of good speech.

Not until the patient begins to distinguish between the faulty and correct sounds does he fully appreciate the importance of attempting to improve upon his own articulation. Hitherto his speech has seemed to him to be the same as that of other people, and he has wondered, perhaps, why he has not been understood. When his ear detects the difference, his whole attitude changes and he begins to manifest great interest in his condition, and to apply himself energetically to the task of improvement; and the rapidity of his progress is often surprising. Frequent repetitions, however, of the correct sounds are necessary to fully establish them in the cerebral centers of speech and to bring the peripheral mechanism of speech under the complete control of these centers.

All that I have said with reference to the treatment of the articulatory forms of defective speech is applicable also to the treatment of stammering. Stammerers may or may not have marked articulatory defects, but like all other people having had no special speech training, they have no voluntary control of the peripheral mechanisms employed in speech. These mechanisms and the muscles that control them are automatic in their action. If I were to ask you to describe the physiology of any one of the elementary sounds of the alphabet as given above, you would have difficulty in doing it because you do not know the action of the numerous muscles that control these mechanisms. The fact is that only a few of these muscles are under the domain of the will, and in the majority of stammerers, they are all involuntary.

Now, why does the stammerer stammer, and what actually takes place in these peripheral mechanisms of speech during the stammering? The patient himself cannot answer these questions. He does not know why he stammers, nor does he know how to avoid it. He only knows that he is never sure of perfect freedom in speech. I can think of no other condition quite analogous to that of the stammerer; he knows what he wishes to do, but he cannot do it. In the functional articulatory form of defective speech, such as I have described, there is merely an arrested or delayed development of the speech faculty. This faulty development would never be recognized by the patient if his attention was not especially called to it by the fact of his not being understood. The stammerer, on the other hand, is fully conscious of his defect, but he has no power to remedy it. His difficulty is not with thought, but with the expression of thought. He thinks in words, but he cannot speak in words. It is almost generally conceded that the primary revival of word memories takes place in the auditory centers of the brain and, simultaneously, but to a lesser degree, in the visual centers; and the molecular activity thus aroused is transmitted with greater or less intensity to other portions of the cerebral cortex. When words are to be written, the impulse is directed chiefly toward the chirokinesthetic center; and when spoken, towards the glossokinesthetic or Broca's center; when neither written nor spoken, this impulse may be directed toward the purely intellectual centers where the words are selected and arranged for purposes of silent thinking.

It is true that some patients stammer in this process of thinking, even when no attempt is made at thought expression. In these cases there is a confusion of ideas

such as we all have experienced to a greater or less degree, and it is probably reasonable to suppose that this confusion of ideas, if sufficiently marked and of repeated recurrence, would lead to a hesitation in speech; and in nervous, impressionable children, to more or less severe forms of stammering. All stammerers experience a greater or less confusion of ideas whenever they attempt to express their thoughts in words, and this confusion generally increases as the necessity for the expression of thought increases. There are few stammerers—for instance, who cannot at all times swear; and I do not recall one of the hundreds whom I have examined that has not been able to talk or read freely when alone or in the presence of dumb animals. In the majority of cases, the greater the desire for speech the greater the difficulty. This is not always true. Occasionally we find one who requires only the stimulus that comes from an important occasion to overcome the barriers of speech. The confusion of ideas of which I have spoken is not always the cause of stammering, but in some cases it is the effect, and the cause must be looked for in the peripheral or conducting mechanisms of speech. When the glosso-kinaesthetic center receives the command transmitted from the other speech centers, it should immediately and automatically execute it. This it oftentimes fails to do, and this failure naturally results in a confusion in the molecular activity of the cortical centers. This automatic and almost instinctive power existing in the conducting apparatus is undoubtedly inherited in greater or less perfection. The ready acquirement of the faculty of speech in children in the second year would never be possible were it not for the operation of this law of inheritance. There are well-authenticated records of development of speech having been delayed for several years in children, and then of whole sentences having been uttered spontaneously and at once, without any previous effort at speech. This would seem to prove that the law of inheritance is especially operative in the transmission of the faculty of speech. Moreover, the clinical records of all these functional disorders of speech furnish additional and stronger proofs of the operation of this law. In almost all cases of defective articulation, and in a large percentage of cases of stammering, the defect may be traced directly to some ancestral origin.

From what I have said we must not conclude that stammering is always of central origin. The cerebral conditions described above are often induced by a derangement in the conducting nervous apparatus of speech. The motor processes of speech are carried on mainly in the bulb and spinal cord, and anything that interferes with these processes will naturally result in disordered speech. This is probably the physiologic explanation of the fact that stammering is often brought on suddenly by a severe shock to the nervous system. To the child who has inherited a predisposition to stammer, a fright or a fall may precipitate the condition; and in like manner the acute diseases of childhood, especially the febrile diseases which affect the nervous system, are fruitful causes of this affliction. These motor processes of speech may also be deranged by obstructions to the normal action of the peripheral mechanisms. Glandular enlargements in the pharynx and all the various conditions occluding the nasal passages, render the use of these mechanisms more difficult, and interfere with their natural automatic action. When this takes place, it reacts upon the conducting motor centers, and this in turn reacts upon the cortical

centers of speech, the whole resulting in a lack of harmony in the action of all the centers (cortical and sub-cortical) employed in the production of language and its expression by articulate speech. Stammering, therefore, is a complex phenomenon. It appears in various forms; no two cases are exactly alike, either in their etiology or external manifestations. This being so, the treatment, like the treatment of any disease, must be adapted to the individual.

In all cases the nose and throat should be carefully examined and all irregularities, either of a structural or a pathologic character, should be corrected. A free action of the tongue should also be made possible by the snipping of a short frenum, and, if necessary, by a division of the anterior fibers of the geniohyoglossus muscle. Of course, the many empiric operations performed upon the tongue for the relief of stammering half a century ago have long since been discarded and no one thinks of employing surgery now except to correct actual deformities of the organs or to remove pathologic obstructions.

Aside from these simple surgical measures which are rather more preventive than curative, and aside from general tonic remedies to support the nervous system, the treatment of stammering must be educational. In the vast majority of cases there is no appreciable organic lesion, and the trouble, at least so far as we can now determine, is purely functional. That there is an inherited organic nervous structure predisposing children to this affliction I am convinced, but it is of so slight a character that we have as yet no means of differentiating it. I repeat that the treatment must be adapted to the individual. We must study carefully his physical condition; and I use the term physical in the broader sense, including the whole being. A study of the mental attitudes of the stammerer throws much light upon his condition. Physical education is the treatment, and physical education in its broadest and most comprehensive form. Mental attitudes and nervous tendencies generally may be entirely changed by suitable physical exercise; and it is a well-recognized fact that the development of muscles is valuable only in so far as it develops nerve-power. We must reach the nervous mechanisms of speech through the training of the muscles supplied by these nerves and employed in the processes of speech. The value of this muscle training is not limited to the motor centers of speech in the bulb and spinal cord, but it extends to the cortical centers of the brain.

As I have said, the motor mechanisms of speech are largely automatic in their action; and when they fail to work automatically, as they do in the case of the stammerer, an effort is made to force them into action. This proves to be an impossibility and results in the various grimaces and other contortions so characteristic of the stammerer.

The proximate cause of stammering, therefore, exists in a functional derangement of the nervous mechanisms of speech, and this condition results in an inharmonious and incoordinate action of the hitherto automatic peripheral mechanisms. The task before us is manifestly to restore the nervous mechanisms of speech to their normal condition; and at the same time to reestablish a normal automatic action in the peripheral mechanisms. There is but one rational and scientific method by which this may be accomplished. The normal functional activity of the cortical centers can only be restored by physiologic exercise, and this exercise can

only come as the result of a conscious effort on the part of the patient to gain voluntary control over the entire muscular system,—giving especial attention to those mechanisms immediately concerned in the processes of speech. The aim, then, in all cases should be toward the volitional control of muscles, keeping in mind that the chief object to be accomplished is the restoration of normal functional activity in the nervous system. Some little ingenuity is necessary to determine just what particular exercises may best suit individual cases; and great patience and perseverance are needed in their application. Of course, the busy doctor cannot do it, and the average teacher will not do it successfully because he fails to appreciate the application of the exercises to the case under consideration; and he lacks, therefore, the incentive to persistent and hopeful effort. Specially trained assistants (not necessarily elocutionists) are required, and they must work in entire harmony with the physician. There must be no differences of opinion with reference even to the details of the work, for this has a bad effect upon the patient. Those having defective speech, and particularly those who stammer, need encouragement and moral support; and attention to little things is of the greatest importance in their treatment.

THE SUMMER COLD: SWIMMING POOLS AS AN ETIOLOGICAL FACTOR.

By LAWRENCE F. FLICK, M.D.,

of Philadelphia.

THERE is a popular saying that a summer cold does not get well until cold weather sets in. I had always looked upon this kind of a cold as a myth until the past summer, when a singular experience strengthened a conclusion which has long been crystallizing in my mind that a popular verdict is always based upon truth.

In the early part of July I took my family to the country, but was driven home within a week by a whooping-cough scare. We remained home for the length of time of the incubation period of whooping-cough, and then decided to remain home for the entire summer. We were informed afterwards that the case at which we took fright was not one of whooping cough. As part compensation for our summer trip away, I took out 5 season tickets in a swimming school, on August 2. Four children and myself used these tickets. The ages of the children were approximately 7, 10, 12, and 14 years. The two older children could swim a little, the two younger and myself practically could not swim any. The swimming school to which we went is one of the best in Philadelphia, and is attended by the better class of people. The water in the pool is filtered and there is a running stream in and out of the pool during swimming hours. I am inclined to think that the inflow and outflow of water is stopped during hours when the pool is not used, as I have, on a number of occasions, gone to the pool in the morning before the inflow had been started. I have been told that the pool is thoroughly cleansed once a week. I have also been told that it takes about 24 hours to completely change the water in the pool. For the correctness of these statements I can not vouch. The rules of the swimming school forbid spitting into the water and also using the water for cleansing purposes.

After we had been going to the school about one week a report was brought home by the children that some of the young swimmers had a croupy cough. This rather prepared my mind for an attack of follicular tonsillitis or possibly a cold in some or in all of us: I did not anticipate anything more serious, however. Some time near the end of our second week of lessons, the youngest child, a boy, was taken with what appeared to be follicular tonsillitis. He had high fever for 48 hours, almost constant vomiting, obstinate constipation, and severe abdominal pains. His tonsils were swollen and the follicles were filled with a whitish substance. After the fever had subsided and the gastric abdominal symptoms had disappeared he was left with a croupy cough and a rather intense inflammation of the nasal mucous membrane. Gradually this condition gave way to a chronic nasal inflammation with free discharge of purulent matter and a gradually increasing cough and expectoration.

I myself nursed the little fellow, and on the second day of his illness I noticed a sore feeling in one nostril far back. The nasal passage on the side affected was completely occluded. The sore feeling gradually extended over a larger surface, and together with the obstruction gave me much discomfort, but apparently set up no other symptoms of disease. I concluded that I had contracted a mild attack of the disease which was afflicting my boy. Aside from the pain and discomfort I suffered no inconvenience. In fact I felt myself to be in unusual good health. Annoyed by the nasal obstruction I made persistent effort to open up the closed passage by douches of antiseptic solution. I used Seiler's antiseptic pastiles for this purpose. I succeeded in clearing the passage, and immediately thereupon I began to notice the soreness rapidly extending into the pharynx, into the trachea, and into the other nostril. Within 24 hours the entire upper respiratory tract was inflamed. Now for the first time constitutional symptoms began to show themselves. These consisted of a slight chilliness and a feeling of lassitude. My appetite continued good. For a week I continued going to the swimming pool irregularly, and I seemed to get some benefit from the water. Gradually, however, the inflammation extended down further in the bronchial tubes, into the antrums of Highmore, into the eustachian tubes, and to some extent into the frontal sinuses. A good deal of frontal neuralgia developed. There were few constitutional symptoms, however. I became rather sensitive to cold, perspired freely upon the slightest exertion and felt an incapacity for occupation of any kind. I now discontinued my visits to the pool. At the end of two weeks my ailment had assumed a chronic form, which changed into a subacute one when I exerted myself much and returned to a chronic one when I rested. Medication seemed to have practically no effect. I used many drugs internally and locally without apparently changing the character or course of the disease. As soon as I noticed that exertion aggravated the condition I remained as quiet as possible without lying up. The discharge from the antrums and frontal sinuses became very profuse, necessitating the use of from 15 to 20 handkerchiefs a day. It was purulent in character. The only remedy which appeared to have any effect upon it was a douche of a solution of tannic acid and chlorate of potash in glycerin and rose-water, which I began to use about the end of the third week.

This materially lessened the amount of the discharge. The disease, however, continued until late in the fall.

About the time that the disease began with me it also started in the other three children, there however being a few days interval between the attacks of each, beginning with the youngest. The youngest, being the second youngest of the four children, had quite a severe attack, having to go to bed with fever for nearly a week. The next older had to go to bed for a few days and had some fever. The oldest had a slight fever for a day, but did not have to go to bed. In all of the children the symptoms were practically the same after the first few days, namely, frontal neuralgia, earache, slight deafness, obstruction of the nasal passages, slight croupy cough, reddening of the eyelids with slight suffusion of the conjunctiva, purulent discharge from the nose, and a feeling of lassitude. There was practically no cough at night, but always severe cough upon arising in the morning and some cough during the day. Some of the children lost their appetites for a few days, but as a rule the appetite remained good. As with myself so with the children, remedies, with the possible exception of the tannic-acid mixture mentioned, were of no avail. The most striking effect of the disease upon the appearance of the children was the production of pallor. Towards the end of the attack the appetite became capricious, but all continued to eat and none lost weight.

At the end of from 6 to 8 weeks we all began to show great nervousness. I myself looked well at this time and had gained in weight, but was on the point of nervous prostration. I was almost totally incapacitated for work. All energy seemed to have left me.

As the cold weather came on we all rapidly improved, but whether this was due to the weather or because the disease had run its course, I am not prepared to say. There remained with some of the children and myself a tendency to congestion of the mucous membrane of the nose which continues with us to this day. One of the children, who was then 10 years old, moreover completely broke down after going to school a month or six weeks without any apparent cause. She became exceedingly nervous, developed complete anorexia, and emaciated rapidly. From this condition she is now slowly recovering. It is but proper to say, however, in this connection that she has been getting a number of second teeth.

An interesting point in the etiology of this disease, which may in part be deciphered from this unique experience, is infection. The disease is evidently infectious rather than contagious, although it may be both. I am convinced that we all contracted the disease directly from the water. My reasons for arriving at this conclusion are as follows: 1. The severity of our attacks was in proportion to our inability to swim and consequently to the extent to which we sucked water into the upper air-passages in trying to breathe under water. I remember distinctly having had an unusually unpleasant experience of this kind a day or two before my attack began. The youngest child, a courageous little fellow, inhaled water quite frequently, and he was the first to develop the disease. The oldest boy, who could swim some and who knew something about breathing while swimming, had the mildest attack. He did not develop his attack until about the time when he began to learn to dive. 2. There were five members of our household, namely, my wife, two younger children, and two maids, who did not take swimming lessons.

My wife and the two children were in intimate contact with the rest of us and the two children on several occasions were at the swimming school as spectators. The maids were in contact with us likewise, although of a less intimate character, and one of them was repeatedly at the school as a spectator. The incubation period of the disease, if our experience may be used to determine it, could not well be over two weeks. At the end of four weeks of intimate association the two children who had not taken swimming lessons, developed a mild attack, and at the end of five weeks my wife developed a mild attack. The two maids did not contract the disease. There was ample opportunity for infection of my wife and the two children through kissing, use of towels, and use of eating and drinking utensils, so that it is quite possible that they contracted the disease by infection. Contagion cannot be excluded, however. The fact that the maids did not contract the disease would seem to indicate that if it is contagious it is very mildly so.

It would be interesting to know how many of the patrons of the swimming school got the disease. One of the attendants told me that a great many people who came there had the same ailment which I had. A friend, who was going to the school with his two daughters at the same time we were, has informed me since that he and his daughters contracted a cold there which lasted them all summer. Two gentlemen, one a physician and the other a clergyman, have since informed me that when they took swimming lessons at this school during another season they contracted colds which lasted all summer. A physician has told me since that he has frequently treated colds which had been contracted at the school, but that he had looked upon them as the result of exposure in wet clothing.

I regret that I am unable to accompany these clinical observations with a bacteriological study. Unfortunately I was unsuccessful in my efforts to find a competent bacteriologist in the city at the time. Cultures from the nasal discharges of myself and children, together with a bacteriological study of the water in the pool, would no doubt have revealed the microorganism which produced the disease. An opportunity for such a study will undoubtedly present itself during another season, when perhaps some of our bacteriologists will be on the lookout for this undiscovered microbe.

Relation between the Occurrence of Appendicitis and the Presence of a Neurasthenic Tendency.

—Schaumann (*Deutsche medizinische Wochenschrift*) refers to this. He has frequently observed appendicitis in general members of neurotic families, and in a number of instances has seen appendicitis appear without any very apparent reason after severe neurasthenia had existed for some time. The fact that appendicitis is not infrequently combined with mucomembranous enterocolitis in his belief shows also some relation between appendicitis and neurosis; likewise neurasthenia is frequently combined with ptosis of one or more of the abdominal organs, and it may readily be believed that alteration in the position of the abdominal organs may lead to appendicitis and that the appendix itself may be out of position and thus be more subject to inflammation; it is well known that in appendicitis the appendix is not infrequently found in peculiar positions. Also, certain authors have expressed their belief that chronic appendicitis is a very frequent result of movable right kidney. Schaumann does not insist that he has proved a direct relationship between neurosis and appendicitis, but he does believe that appendicitis may in some instances be the result of general neurosis, usually indirectly. [D.L.E.]

Experimental Pancreatitis.—It is no discredit to the fair reputation of our predecessors in medicine that the knowledge they possessed of the pancreas and its morbid conditions should have been vague and inaccurate. Before 1642, at which date Wirsung discovered the pancreatic duct, thus proving the glandular nature of the organ, it had been the habit to attribute to diseases of the pancreas such conditions as melancholia, ague, and hypochondriasis (Fernelius). And indeed, notwithstanding Wirsung's discovery, it has not been until recent years that anything like a proper knowledge of the physiology and pathology of the pancreas has been acquired.

There is no organ of the body that is so uncommonly the seat of idiopathic disease, and it is certain that no other pathological process presents a greater variety of inconstant and contradictory symptoms. Within the past few years, however, experimental work, on the one hand, and careful pathological study on the other, have evolved some order out of the chaos, and a vast deal is now established with much left unsolved.

We have to recall only the situation of the pancreas, its intimate relations with surrounding structures, and the great rarity of uncomplicated pancreatic disease, to understand the nature of the difficulties which beset a student in both the subjective and objective signs of morbid action.

Dr. Simon Flexner has lately conducted a series of experiments upon the pancreas, the report of which will be found in the *University Medical Magazine*, for January, 1901. They amplify this investigator's previous work in the same field (1897), and form a valuable contribution to our knowledge of the subject. With a view of studying the effects of injury, and of chemical substances, as well as of the various bacteria, upon animals, inoculations were made into the duct as well as the gland substance proper. Flexner gives us a résumé of his former work, and the results of other experiments than his own. While a great deal of light has not been thrown upon the causes of pancreatitis, the nature and causes of fat-necrosis have been established definitely. Flexner's conclusions from his earlier paper bear repetition. He states that the pancreatic secretion may enter the peritoneal cavity without setting up diffuse inflammation, but in a certain number of instances sterile pancreas or its secretion causes local

fat-necrosis. The element of infection plays a very insignificant part. In peritoneal fat-necrosis the fat-splitting ferment is demonstrable in certain stages of the pathological process, being present in greatest amount early, and it may disappear as healing advances. Flexner believes that it is highly probable, but not proved conclusively, that steapsin is the direct cause of necrosis. Finally, the escape of the pancreatic secretion into the peri- and para-pancreatic tissues is the origin of the necrosis, and this escape is facilitated, not only by lesions of the pancreas, but by disturbances of its circulation, which include the effects of injuries inflicted upon the gland as well as the results of passive congestion. The valuable work of Oser upon this subject is referred to by Flexner, and Oser's classification of diseases of the pancreas is adopted. He enumerates: (1) Acute hemorrhagic pancreatitis, (2) suppurative pancreatitis, (3) necrotizing pancreatitis, and (4) chronic indurative pancreatitis. Experimental work has thrown much light upon the suppurative and necrotizing varieties, and in those cases in which the pancreatitis does not produce the death of the animal, the chronic indurative form is seen to follow. As a result of Flexner's experiments, he concludes that hemorrhage *per se* is a common condition of all forms of pancreatitis, and that when it is excessive it dominates the process. It is more pronounced usually in inflammatory lesions, and the two conditions may be separate and distinct in the same organ, or parts of the organ. Fat-necrosis is due to the perversion of the pancreatic secretion and is the direct result of the action of the fat-splitting ferment. He calls attention to the fact that owing to the severity of the means employed to provoke pancreatitis in experimental cases, it is not found that hemorrhage occurs commonly independently of the inflammation. The part which infection plays is probably secondary to the action of the pancreatic secretion upon the injured foci.

There are many phases of this subject which we cannot touch upon within the scope of these remarks. It is, however, suggestive to enumerate some open questions, such as the relation between diabetes and diseases of the pancreas, the nature of the leukemia present in animals experimented upon; the relations between the spleen and the pancreas and their functions; and, finally, the relations between the liver and the pancreas. We would call attention in this connection to a

paper by Opie which appeared in the *American Journal of the Medical Sciences*, for January, 1901.

Contempt of Court versus Contempt of Human Life.—Judge Wiltbank, of the Criminal Court, in this city, pronounced an opinion last week which is likely to have an educational effect on the public at large and on physicians in particular. In imposing a fine on a tardy doctor, who had been detained at the bedside of a patient critically ill, the learned judge is reported to have said that it were better that the patient had died than that the Commonwealth should be treated with contempt. He afterwards graciously remitted the fine, but did not reverse his own opinion; and so the record shows that a Philadelphia judge, if correctly reported, values the dignity of his court above a human life. That every doctor will dissent from this preposterous opinion is happily certain, for the physician, we believe, does not practise in this city to-day who would not rather pay this fine many times over than desert a patient *in extremis*. The incident throws a curious light on the exaggerated importance which some of the courts attach to their own prerogatives. The truth is that the courts, more than all our other institutions, inherit the traditions of the dim past. They claim a great antiquity, which lies in remote English history, when the judge upon his bench was little less sacred than the king upon his throne. Thus Blackstone in his Commentaries (Book III, Chapter 3) tells us that the judge represents the sovereignty of the king, and that in the contemplation of the law the king is supposed to be always present in court. From this fiction arises the great atrocity of contempt, for to be in contempt of court was really to be guilty of a form of lèse majesté. In modern times, and in a democratic community, such a prerogative is not accorded to the courts, especially here in America; and when the value of a human life is set opposite to the interests of an assault and battery case, we doubt not that the sympathy of the public, as well as its common sense, will side with the doctor. Still, we suppose Judge Wiltbank is entitled to such vindication as he can obtain from the traditions of the bench.

A Reminiscence of the Queen.—In its memoir of Queen Victoria, the *British Medical Journal* recalls an incident in her life that is full of interest for medical readers. In 1853, at the birth of her son, the late Duke of Albany, she submitted to be placed under the influence of chloroform. This anesthetic was administered by Dr. John Snow, and was given in doses of 15 minims, the Queen being kept under its influence during her accouchement for nearly an hour. This was at a time when chloroform, especially in obstetrical practice, was still regarded with the greatest suspicion, and even abhorrence. Eminent members of the profession denounced its use as not only dangerous, but unjusti-

fiable, and some of them even went to the fanatical extreme of proclaiming that the use of an anesthetic in labor was a defiance of the Almighty, who had pronounced upon all women the primal curse that they should bring forth their children in sorrow and pain. This battle raged here in Philadelphia as fiercely as in England, and reputations were, for the time being, nearly marred by it. Sir James Y. Simpson, who championed the advent of chloroform, used and advocated it especially in obstetrics, but it was made to suffer opprobrium for nearly all the accidents, from whatever cause, that can happen in childbed. It was accused, for instance, of causing puerperal insanity, and several papers or references on the subject were contributed to medical literature. In a case happening near Philadelphia, in or about 1853, legal complications were barely averted, the doctor in the case having administered the new anesthetic, and the patient a few weeks later having gone insane and been taken to Kirkbride's. It is difficult for us to realize in the present day the unreason and prejudice displayed against this beneficent practice, and to fully appreciate the courage of Queen Victoria and her confidence in her physicians, as well as the confidence of her physicians in themselves, in thus resorting to the use of an almost unknown and apparently deadly vapor. It is needless to say that the example of the Queen was of the greatest influence in England, and presumably in the world at large. Chloroform had undoubtedly begun to be used before this date, but its use under such august and auspicious circumstances was the one thing needful to bring it into vogue.

Huxley and Leidy.—These two eminent scientists, who are of special interest to our readers because they were both members of the medical profession, are brought prominently into notice, the former by the biography and memoirs of him that are appearing, and the latter by the presentation of his portrait to the College of Physicians here in his native city. It is much to be regretted that the tribute of a well-written life, such as has just appeared of Huxley, has not yet been paid to the memory of Leidy. Surely there was enough in that fruitful and profound life—even though it were a comparatively uneventful one—to make a deeply interesting book. Leidy, unlike Huxley, remained identified with the medical profession all his life, and spent his invaluable days in the routine work of teaching practical anatomy to medical students. In the light of what we know of him, and of what he did, this life-work, though a sufficiently noble one, must be looked upon as something of a sacrifice. He had the genius of a great morphologist and paleontologist, and his contributions to these sciences are sufficient evidences of the vast work he might have accomplished if he, like Huxley, had devoted more of his life to purely scientific work instead of to the work of medical edu-

cation. However, the long line of students who for forty years sat at his feet, were the gainers, not only in practical knowledge, but in the benefit derived from the example and personality of a great scientist.

Lord Avebury (better known as Sir John Lubbock) in his recent memorial lecture on Huxley, delivered before the Anthropological Institute (*Popular Science Monthly*, February, 1901), has depicted the best and most lovable traits of the great "agnostic." Huxley invented this term to describe himself, but it represented his logic rather than his sympathies. These latter never hesitated to go forth even where his reason could not always follow. He was many-sided, and his versatility, as Lord Avebury shows, expended itself in three main channels—science, education, and metaphysics. In all these spheres he was, when need be, a controversialist of the highest and best type. That these two great men, Huxley and Leidy, knew and thoroughly appreciated each other, is shown by not a few interesting records and relics. Huxley, speaking of himself, says that when he was a medical student he resolved "to make the best of the stuff" that was in him. He succeeded so well that from the beginnings as a medical student he ended by becoming one of the foremost thinkers, investigators, and expounders of his day.

Neuroses of the Stomach.—For many years it was customary to write at length of purely nervous gastric affections. Recently there has been a strong tendency in the opposite direction, and some authors even deny the existence of purely nervous chronic gastric disturbances, insisting that these always have an anatomical basis. The view at present adopted, however, by the most clearheaded of those interested in gastric diseases, is that if a purely nervous chronic disturbance of the stomach occurs it is extremely rare, but that on the other hand gastric disturbances not infrequently have primarily a purely nervous origin, and, secondarily, through the effects of the functional nervous condition, anatomical changes in the stomach occur. The essential point insisted upon is that it is almost always erroneous to consider a protracted gastric disturbance purely nervous, since anatomical changes almost inevitably occur in the stomach as the result of prolonged functional disturbance. There seems indeed to be but one satisfactory case on record in which marked disturbance of gastric function occurred throughout many years without producing distinct anatomical changes in the gastric mucous membrane. The most common results are probably well exemplified in a recent interesting report by Ferrannini (*Centralblatt f. innere Med.*, January 5, 1901), who describes a case in which there has been for 11 years frequent attacks of what at first was evidently, from the symptoms, an intermittent gastrosuccorhea, and which, during the latter course of the disease, had become a continuous gastrosuccorhea. The case ended with a severe attack of tetany which soon proved fatal. The micro-

scopic examination of the stomach demonstrated the apparent course of events. The changes in the stomach were widespread, but distinct stages in these changes could be followed clearly. The earliest alteration was in the parietal cells; these had increased in number, they were enlarged and swollen, and there was some dilatation of the glandular cavities and outlets. In later stages the increase in the number of the parietal cells and in their size became much more marked, and most of the cells contained two nuclei; the principal cells had become shrunken and decreased in number, and their protoplasm was of a homogeneous appearance. In more advanced stages the changes in the purely glandular tissue were even more marked, and there was also some increase in the connective tissue, with moderate round-cell infiltration. The most important part of the observation was in the fact that the changes in the glandular cells were so very widespread and so far advanced, while inflammatory changes had appeared late. That such changes should have been so marked and protracted as the result of actual gastritis, while the connective-tissue remained uninvolved, seemed highly improbable, and the only proper conclusion seemed to be that the condition was at first purely irritative and consisted of swelling and hyperplasia of the HCl secreting cells, and that secondarily to this the interstitial tissue showed changes. That the inflammatory changes were secondary seemed evident from the fact that they began about the free surface of the gastric mucous membrane and not about the glands. They were therefore evidently the results of the irritation of the stomach from its own excessive secretion, and from the stagnation of stomach-contents following the pyloric spasm which this secretion produced. It seemed clear, then, that the disturbance in this case had been at first purely functional and not inflammatory, but that ultimately the prolonged irritation had in an indirect manner produced an actual gastritis. The case is reported chiefly in its relation to the interesting question whether a gastrosuccorhea ever occurs without a gastritis or a pyloric stenosis. Most writers consider now that there is always one of these anatomical changes present. This report seems to show that this is not necessary, for, as stated, the gastritis seemed to have been a late occurrence in the case, and there was even at the time of death no stenosis of the pylorus, so that a Reichmann's disease of purely nervous origin seems to be wholly possible and even probable. Another fact of great interest in the case is that severe lesions were found in the nerve cells of the medulla and cervical cord, the lesions having the characteristics of those found in severe toxic conditions. These changes Ferrannini considers to be important testimony in favor of the view that tetany is a toxic condition and not that the symptoms are purely reflex. This view has already received the sanction of the majority of those interested in the question.

A Crusade Against Illegal Practitioners.—It is the purpose of the Medical Society of the County of New York to begin an active crusade against the unlicensed and therefore illegal and unscrupulous practitioners of that city, and the society asks the cooperation of the profession and the public generally. From a circular issued by the committee, of which Dr. Frank VanFleet is chairman, and Dr. John VanDoran Young is secretary, we learn that the medical laws of New York provide that before one can practise medicine in that State a certificate of proficiency shall be obtained from the regents of the university of the State, which is given only after a satisfactory examination. The purpose of this movement is to protect the people from incompetent practitioners of medicine. There are many irregular practitioners in New York City who practise in open defiance of law apparently without molestation.

It is needless to say that we are in complete sympathy with the object of the society in this matter. Philadelphia has her own troubles of a like nature to contend with, and we trust that the action of the Medical Society of the County of New York will not only be successful but will be an example for the medical authorities of all our large cities to imitate. Practitioners of medicine are properly protected by the law, not however for their exclusive benefit, but first and above all for the benefit of the public. The public itself will not, or does not, always recognize this fact, and it can only be properly kept advised of it by the action of physicians themselves who must of necessity constitute themselves guardians of the law. We shall look with interest for the results of this crusade.

Racial Predisposition to Pulmonary Tuberculosis.—In illustration of the racial susceptibility to pulmonary tuberculosis, it may be pointed out that from 1884 to 1890 it is estimated that among every 100,000 of the population there occurred annually in New York 238.48 deaths from pulmonary tuberculosis in white natives, 483.83 in white foreigners, and 774.21 in colored persons. Jews, on the contrary, appear remarkably exempt from the disease, 36.57 deaths being due to pulmonary tuberculosis in every thousand deaths among them in the United States in 1880, as compared with 108.79 for the general population.

According to a communication in a recent number of the *Revue d'Hygiene et de Police Sanitaire*, by Tostivint and Remlinger, only 34 of the entire number of 2,744 deaths among the Jews of Tunis in the five years from 1895 to 1899 were due to tuberculosis—1.24 per cent. It is further estimated that the average annual mortality from tuberculosis among the Mussulman Arabs between the years 1894 and 1900 was 11.30 per 1000, among Europeans 5.13 per 1000, and among Jews 0.75 per 1000. The lower mortality from tuberculosis among the Jews is not attributed to ethnic differences, nor to peculiarities in food, dress, and the like, but

rather to their abhorrence of the dusting brush, damp cloths being preferred for wiping soiled surfaces, and to their frugality in the use of furniture.

Why there is No Malaria in Buffalo.—The city of Buffalo is apparently to be congratulated on its freedom from malaria, and this freedom, as would naturally be supposed, is entirely due to the fact that there are few anopheles mosquitoes in that city or its environs. Dr. Irving P. Lyon, assisted by Mr. Albert B. Wright, has been making a systematic study of the subject, and has just published a preliminary statement in the Report of the Laboratory of Pathology of the University of Buffalo. The mosquitoes gathered for this study were found in and around the city, and the fact that only 374 of these insects were caught in six months is in itself an evidence of the salubriousness of Buffalo as a place of residence. Of this number all were of the genus *culex*; in other words, not one of the pathogenic or malaria-bearing *anopheles* was found. Moreover, all but 17 of the specimens were females; and as the females are reputed to be the real blood-suckers, the observations were not lacking in appropriate material. The city of Buffalo, it is pointed out, is situated on the shore of Lake Erie, 573 feet above the sea level, in a country that is sparsely wooded and the seat of few swamps, marshes, and low-lying places. Hence, this region is not what would generally be called a malarious country. And, in fact, according to the observations of Dr. Lyon and Mr. Wright, the city is remarkably exempt from malaria. Offers were made to examine without expense the blood of all persons in public or private practice who were suspected of having malaria, and in not one instance was the plasmodium found. The authors, therefore, conclude quite legitimately that autochthonous malaria does not exist in and around Buffalo. What cases have been observed there in the past have apparently been imported from other places. This comfortable assurance, however, is somewhat rudely shaken by a postscript in which Dr. Lyon and Mr. Wright acknowledge that since their own search, Mr. Adams, a local entomologist, had discovered a few anopheles in Buffalo.

This investigation by Lyon and Wright is interesting not only in itself, but also as an evidence of the widespread concern now being felt for the whereabouts of the anopheles mosquitoes and of the thoroughly scientific way in which the problems of malaria are being worked out.

The Venereal Diseases of the Lower Animals.—The advance of science has gradually shorn man of his preeminence to the other animals. Waldeyer has shown that his spinal cord is not so greatly different from that of the gorilla; Romaner, that his mental processes represent merely a higher development of qualities that exist among the vertebrates. Whether the higher insects

possess a different psychology we do not as yet know. But for one thing man has always been supposed to be distinct. No lower animal has ever been inoculated successfully with syphilis, and, in the venereal diseases at least, we supposed that we stood alone. It is true that many experimental physiologists have observed, not infrequently, a drop of pus exuding from the urethra of the common cur that was the victim of their experiment, and we know that the toxin of the gonococcus will kill mice, if bouillon cultures are injected into the peritoneal cavity of the animals, but the one is not certainly known to be a contagious malady, and the other is merely a manifestation of the toxic property common to many bacteria.

It was not so long ago, however, that in an excellent study, published in the *Journal of Pathology*, Smith and Washburn described a form of infectious granuloma that occurred among dogs, attacked the sexual organs as a rule, was contagious by inoculation, and usually transmitted from one individual to another during coitus; and they further expressed the opinion that similar diseases had already been observed and described, although incorrectly interpreted, by Duplay and Cazin, Wehr and Geissler, and, we might add, by Moreau and Human, although the careful histological studies made in these instances point strongly to tumor formation.

More recently, Marek (*Neurologisches Centralblatt*, December 15, 1900) has described a disease of horses, which, unless he was so prejudiced as to be incapable of accurate observation, bears so many ear-marks of syphilis, that it must belong to the same category of ailments. The first manifestations are upon the external genitalia, and consist of small nodules or erosions upon the mucous membrane, appearing from a few days to several weeks after sexual intercourse. Next there is a papular eruption upon the skin, and, finally, a peripheral degenerative neuritis, which ultimately causes the animal's death. The most important feature of the whole matter, and one that Marek appears to have overlooked, is the possibility of making more thorough studies of this condition, with a view to the discovery of the cause, than can be undertaken with reference to syphilis in human beings, and it is scarcely necessary to point out that such a discovery might—we had almost said would—be of incalculable benefit to simple humanity or its inheritors.

Intussusception Caused by a Melanotic Sarcoma of the Small Intestine.—Smole (*Zeitschrift für Heilkunde*, Bd. xxi, Heft 9) reports a case of a woman in whom a melanotic sarcoma of the small intestine almost occluded the whole lumen of the affected portion of the gut. There was a history that a melanotic sarcoma, the size of a fetal head, had been removed from the arm a short time previous. No intestinal symptoms have appeared, one year after the operation. [M.R.D.]

Reviews.

Physical Diagnosis in Obstetrics. A Guide in Antepartum, Partum, and Postpartum Examinations. By EDWARD A. AYERS, M.D., Professor of Obstetrics in the New York Polyclinic; Attending Physician to the Mothers' and Babies' Hospital. Pp. 283. New York: E. B. Treat & Co., 1901.

The foundation or underlying motive of this book is the brief systematic discussion of every point of physical diagnosis bearing upon the parturient condition. It has developed from the writer's teaching experience. He argues that the self-training of the physician demands the same explicit and systematic method as the teaching of the student. An elaborate examination or history chart is presented which carries out this idea by suggesting in print the minute details of possible conditions, thus: Edema in right, left, foreleg, thigh, vulva. Fetal heart heard, right, left, above, below, umbilicus. In using the chart all items not observed are to be crossed out. This makes each examination a factor in observation-training, though the resulting page is not neat and the facts are not easy to group.

With this chart for a skeleton analysis the book is constructed by briefly discussing each minute point in turn. Extended by adding the child's history and the maternal postpartum history, the result is a succinct discussion of physical diagnosis in the entire obstetrical field, viewed from a simple practical standpoint, which avoids as far as possible disputed ground. An indispensable index is supplied. [W.A.N.D.]

Modern Medicine. By JULIUS L. SALINGER, M.D., and FREDERICK J. KALTEYER, M.D. Philadelphia and London: W. B. Saunders & Co. Price in cloth, \$4.00, net.

The task confronting the authors of this book was an heroic one—that of furnishing within the compass of some 800 pages a comprehensive treatise upon modern medicine. That their efforts have resulted in producing a work within these limits which takes its place with the greater textbooks and not with compends or manuals is a sufficient guarantee of the mastery of facts and the industry of the authors. The material has been drawn from all available sources, especially from authoritative works in French, German, and English. The consulting of this broad bibliography has resulted in a very acceptable presentation of facts, without the teaching of any particular clinician having been followed lavishly.

There is a great deal to commend in the work and but little which arouses a spirit of criticism. We might have wished to find "typhoid intoxication" mentioned and some of the facts of etiology marshalled less baldly—a fault unsurmountable when space is at a premium. The first 172 pages have been devoted to a concise comprehensive treatise upon symptomatology, semiology, physical diagnosis, clinical bacteriology, and laboratory methods. The idea of grouping together these divisions seems to us a good one. Much subsequent repetition is avoided in discussing the separate diseases.

In the article upon appendicitis the writers have coined the term "evolutionary tendency" in contradistinction to "hereditary tendency," the latter showing itself from generation to generation, the "evolutionary tendency" only upon change of environment. The use of opium in the treatment of peritonitis has been expressed clearly and briefly: "Opium given in liberal amounts is of great value in the treatment of peritonitis. Early in the disease, when the diagnosis is still in doubt, as peritonitis is often due to causes which necessitate surgical intervention, it is sometimes advisable to withhold the opium for a short time, as it will mask the symptoms; but if the diagnosis has been made, or if the diagnosis seems impossible, it is necessary to administer opium freely."

Treatment throughout has been outlined admirably. There is a commendable conservatism and an avoidance of pernicious polypharmacy. The chapters upon malaria and the blood are in every way satisfactory, and the accompanying plates are unusually accurate.

The idea of drawing the blood-corpuscles to a scale and

showing them stained by two methods should prove of value to the student. In the effect at conciseness no cases have been introduced or controversial points considered. The tables of differential diagnosis are well arranged. Last, but not least, the clinical medicine of the book is extremely well presented. The approved methods and the minutiae will surely make the work appeal to the student, who here finds within the compass of the single volume a work upon the practice of medicine and clinical medicine as well. [T.L.C.]

The Use of the Röntgen-ray by the Medical Department of the United States Army in the War with Spain, 1898. Prepared under the direction of Surgeon-General G. M. STERNBERG by W. C. BORDEN, Captain and Assistant-Surgeon, U. S. Army. Washington: Government Printing Office, 1900.

This work, the most thorough and comprehensive that has yet appeared on the application of the Röntgen-ray apparatus to the diagnosis and treatment of gunshot injuries, is based upon Borden's personal experience with the wounded American soldiers of the Spanish-American War.

He believes that the place for the Röntgen ray apparatus is at general hospitals, permanent hospitals on the line of communication, and on hospital ships; that for equipping base, and general hospitals for war service, coil apparatus connected to primary batteries should be supplied; that in permanently established hospitals where there is no dynamo current available, the static machine will probably give best satisfaction; while, in permanent-base hospitals or in hospital ship, supplied by direct currents of 110-120 volts, the break-wheel apparatus will give the highest efficiency.

Attention is called to the fact in the American Civil War, where a much larger caliber rifle was used, and asepsis and antisepsis were unknown, the mortality was nearly double that of the Spanish-American War. Indeed, it is noteworthy that there is a smaller mortality as compared with the number of the wounded in our late war than is to be found in the records of any war since the middle of the last century. The nearest approach to the admirable showing made by our military surgeons is afforded by a study of the Japanese records of the China-Japan War.

In considering the regional distribution and mortality of gunshot wounds in cases which came under treatment in the American Civil War and the Spanish-American War, it is to be noted that the mortality percentage of head-wounds, face-wounds, and abdominal wounds is about the same. Wounds of the neck and spine were attended by a greater mortality in our recent war than is shown by the records of the Civil War. Chest wounds show for the Spanish-American War less than half the mortality of the Civil War. Wounds of the extremities show less than one-fourteenth of the mortality recorded in the Civil War. The number of deaths in the Spanish War from wounds of the extremities is surprisingly small, being but 10 in 901; of these 10 cases, 3 died very shortly after receiving their injuries, probably from hemorrhage. In the Civil War about 7% of those wounded in the extremities were subject to amputation or excision, with an operative mortality of 21.6%. In the Spanish-American War, but 3.2% of those wounded were subject to major operation, and 18.7% of these cases perished. Under conservative treatment the mortality was 9.1% in the Civil War; in the Spanish-American War, 4%. The high mortality of the operative cases in the Spanish-American War is to be attributed to the fact that only extremely serious cases were operated on.

In the chapter on lodged missiles, Borden points out that the jacketed bullet when undeformed almost invariably travels in a right line after entering the body. The large number of lodged missiles seen in the Santiago campaign was particularly commented upon by the surgeons. In 198 Mauser bullet-wounds seen by Borden, there were 21 lodged bullets. It was quite possible that in some cases the velocity of the bullets had been reduced by passage through the branches of trees or by glancing. The fact that the Röntgen-ray apparatus often showed the bullet to be deformed is considered as fairly conclusive of the fact that the bullet had previously struck some solid substance and had glanced therefrom. A number of instructive and interesting cases

are reported in detail with very admirable reproductions of the original x-ray pictures. One particularly striking plate is that of a private, still living, showing a Mauser bullet lodged in the brain. Practical experience has shown that ricochet, passage through bodies, or low red velocity, does not markedly increase the proneness of the jacketed missile to produce infection, and hence the lodgment of a bullet does not necessitate the treatment that would be given an infected wound. They are best treated by occlusive dressings and noninterference unless manifestly infected or unless some special condition calls for operation. It also appears that large lead bullets of low velocity are not as apt to make infected wounds as was supposed.

The third chapter of this book is devoted to the localization of loaded missiles. The method of localizing by direct observation, by multiple observation, and by photographic apparatus, are taken up in detail.

The fourth chapter is devoted to gunshot wounds of the diaphyses of long bones. Some striking instances are given of the explosive effect of the modern bullet at short range. These are fully illustrated by the plates. The treatment of these wounds should be influenced by the presence or absence of infection rather than by the extent of bone comminution. Extensive bone comminution is not as a rule an indication for operative interference of any kind. Occlusive dressings and immobilization give assurance of the best possible results. Even though shortening of the limb should occur, an excellent usefulness may be expected. Where infection necessitates this, the wound must be thoroughly cleansed and all loose bone fragments must be removed; this treatment should be followed by antiseptic dressings and irrigation. It is noteworthy that the amount of bone comminution is much less and the size of the fragments much smaller in gunshot fractures of the extremities of long bones than in gunshot fractures of the shaft. The involvement of the joints does not necessitate a divergence from the rule of expectant treatment.

The final chapter of this book is devoted to radiographic technic. There is an interesting contribution in this relation upon the subject of Röntgen-ray burns. The factors which influence the production of these burns are the length of exposure, the nearness of the tube to the surface of the body, the physical condition of the patient, and individual idiosyncrasy. The exposure should not exceed 30 minutes and 10 inches should be taken as the minimum distance of the tube from the body. Exposures frequently repeated with but small intervals between them will act in the same way as a single long exposure.

This work is a valuable addition to radiographic bibliography, and well worth a place among the publications of the medical department of the United States Army. The last statement is giving it high praise. It is also of distinct value to the hospital surgeon. The conclusions of Borden, which appear to be based on careful, conscientious, and dispassionate study, are likely to be accepted without dispute. [E.M.]

Perforation of the Intestine in Typhoid Fever: Its Surgical Treatment. — N. Manger (*Thèse de Paris*, G. Steinheil, 1900, 128 S.) emphasizes the following points of surgical interest:

Perforation of a typhoid ulcer may take place in every stage of the disease, also during relapses, but generally occurs from the second to the fourth week. It occurs in ambulatory cases as well as in grave ones, and in children as well as adults. Almost always there is one perforation, rarely two are present. The perforation is situated in most cases within the last 60 cm. of the small intestine, in exceptional cases, also in the other portions of the gut from duodenum to the rectum, and, not so very rarely, also in the appendix; it has been observed in Meckel's diverticulum. The diagnosis is not always easy, because in grave cases the symptoms of typhoid fever may mask the perforation. The most important symptoms are sudden pain, acceleration of the pulse, collapse, and later on manifestations of peritonitis; the temperature generally falls, although it may rise or remain stationary. When symptoms of intestinal perforation suddenly arise in an apparently healthy individual, latent typhoid is always to be suspected. The author believes that the treatment should only be a surgical one. Of 107 cases operated upon, he reports 25 recoveries. [M.R.D.]

Correspondence.

THE PERCENTAGE OF SILVER IN SILVER NITRATE.

By WILLIAM J. ROBINSON, PH.G., M.D.,
of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In the paper entitled, "Method for Rapid Elimination of the Gonococcus," by Dr. Follen Cabot, Jr., there appears an erroneous statement which should not, it seems to me, go uncorrected. The author states that silver nitrate contains 6.35% of silver. The actual percentage is 68.5%. We could excuse the author on the score of a typographical error, but the context of the sentence does not permit us to do so. The author states distinctly that protargol contains 8.2% of silver, argonin 4.2%, and silver nitrate, containing 6.35%, occupies a middle position between the two first named preparations in its proportion of the basic salt." As a matter of fact it contains about 8 times as much silver as protargol and about 15 times as much as argonin.

THE PERCENTAGE OF SILVER IN SILVER NITRATE.

By FOLLEN CABOT, JR., M.D.,
of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In answer to Dr. Robinson's criticism of a statement in the article by me entitled, "Method for the Rapid Elimination of the Gonococcus," I will say that the doctor is right in his correction.

It was a careless error on my part. In looking over some literature on the subject, I read a paper by Dr. Edward S. Peck, of New York, entitled, "Protargol and Argonin in the Treatment of Purulent Ophthalmia of Infants," published in the *Medical News*, January 21, 1899. In discussing the subject and giving the amount of silver in argonin as 4.2% and protargol 8.3%, Dr. Peck continued as follows: "In this connection it should be noted that silver nitrate contains 6.35% of silver, occupying between protargol and argonin a middle position as to the basic salt."

I am surprised that the error was not noticed when I read the paper.

INTRACRANIAL HEMORRHAGE IN THE NEWBORN.

By W. W. KEEN, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I was very much interested in reading the paper by Dr. W. Reynolds Wilson, on "Intracranial Hemorrhage in the Newborn," in your issue of February 2. I wish to call attention especially to the paragraph on treatment, for the reason that Dr. Wilson has omitted, what seems to me to be the most important treatment of all, namely, the surgical. In the preceding paragraph on the "prognosis," Dr. Wilson has very properly called attention to the widespread and varied ill results that may follow such intracranial hemorrhage, and has properly indicated the fact that "extensive meningeal hemorrhage is not likely to be absorbed." In view, therefore, of the dangers that he points out, and the improbability of absorption, it seems to me clear that at the very earliest moment that it is safe to do so, such a patient should be trephined and the clot removed.

I cannot but think that obstetricians have overlooked the good that may result from such surgical interference.

At my clinic at the Orthopedic Hospital, I saw not uncommonly the sad ravages caused by such an intracranial clot, and in the other surgical clinics, and especially the neurological clinics of the same hospital, they were, I believe much more frequent. I do not recall any case which has been operated on.

A considerable time ago Dr. Weir Mitchell called my attention to this condition, and we decided that in any suitable case, especially if we could get hold of it at an early date, such an operation was not only justifiable, but demanded.

I have no doubt that it is omitted from Dr. Wilson's treatment for the reason that up to this time, I believe, it has not been done. That it ought to be done, personally, I have not the slightest doubt.

A CASE OF AORTIC ANEURYSM.

By F. W. LARRABEE, M.D.,
of Searsport, Me.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

X., sea captain, age 38; family history, good; previous history, malaria 12 years ago; gastric and intestinal disturbances for 2 years. One year ago on return trip from Hongkong patient had an internal abscess of some sort with spontaneous rupture into the bowel. Recovery good; had since been treated for rheumatism and atrophic liver.

First seen November 27, 1900. Symptoms: Pain in the left hypochondriac region; also in the back to left of the spinal column from the angle of the eighth rib to the sacrum; a swelling over the angle of the tenth rib on left side, about 2 inches in diameter; soft, pulsating, and expansile; pain on pressure along tenth rib; liver displaced downward and to right; the stomach, downward and to left; spleen, downward; dulness over lower lobe of left lung posteriorly; slight bruit over the swelling; pulsation synchronous with heart-beat; expansion with each pulsation; pulse, 80; fair volume and quality; temperature, normal; loss of weight, moderate. Aseptic aspiration of a little fluid from the tumor showed thick dark blood, which under microscope showed blood-cells and fibrin.

Patient advised to go to Massachusetts General Hospital, which he did. Diagnosis of aortic aneurysm confirmed and rest treatment advised.

Patient returned home December 12. Tumor found enlarged to 4 inches in diameter and more conical in shape; pulsation more marked; bruit less distinct; bowels, constipated. Patient suffered great pain at times in left hypochondriac region and left iliac, partially relieved by passage of flatus on giving an enema. Pain seldom felt in tumor. Patient put to bed, bowels regulated and rest secured as much as possible but seldom perfectly; relief from pain only temporary.

The tumor remained about the same until January 2. At that time patient began to suffer pain in the tumor and two days later the tumor was found enlarged upward and downward so that long diameter was about 6 inches and short diameter 4 inches; tumor more prominent. Three days later tumor was found nearly round and about 6 inches in diameter. Intense pain in left hypochondriac and left iliac regions. Tumor swelled so that the skin was very tense and glossy and edematous in places; blebs appeared over most prominent part. Symptoms of cardiac dilation supervened and patient died from exhaustion January 19.

Postmortem examination showed large aneurysm of abdominal aorta arising just below the diaphragm. Liver atrophic and displaced downward and to the right; stomach displaced downward and to the left; spleen downward; diaphragm and left lung crowded upward; necrosis of parts of ninth and tenth ribs; aneurysmal sac 5 inches in diameter which had not ruptured before death.

A CASE OF ANGINA LUDOVICI.

By ARCH D. JONES, M.D.,

of Wichita, Kas.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

HAVING read the report of Dr. G. G. Ross on Cases of Angina Ludovici, it occurs that a report of a case in my practice may be of interest. Although I had never before seen a case, nor have I seen one since, I did not know that it is such a rare occurrence:

Mrs. W., aged 47, had been having an ulcerated lower molar treated. The first disturbance she noticed additional to her tooth was a swelling and burning sensation under her tongue on the same side as the ulcerated tooth. She rinsed her mouth with a preparation given her by her dentist, thinking it might be irritated by the discharge from her tooth; but that did not suffice. In a few hours the inflammation had spread to the tissues under the other side of the tongue. She came then immediately to her dentist, who sent her to me. By that time, on opening her mouth it gave the appearance of having two tongues, the sublingual tissues pushing out and up, almost protruding between the teeth. Her tongue was so much crowded that she could speak with difficulty. She complained of a burning, throbbing sensation in the tissues under the tongue. I found her temperature 101.3°, pulse 102. I sent her home and to bed, ordering the ice-bag applied, and the painting of the inflamed parts every hour with 4% cocain solution. I went promptly to confer with her dentist, advising immediate removal of the tooth and thorough irrigation and drainage of the cavity. The above was done, but still the inflammation continued to advance, the pharyngeal tissues being considerable involved by evening, 14 hours after the first indications of the inflammation. With morning the dyspnea was considerable, but not alarming. The submaxillary and cervical tissues were swollen and painful. The abscess cavity was again thoroughly cleansed, although there was very little accumulation.

At 6 P.M. the condition seemed about the same. The inflammation had not advanced, the dyspnea was about the same. On the morning of the third day the swelling was markedly diminished. The cavity was again irrigated, no discharge being noticeable. The improvement from this on was steady and rapid. There was suppuration in the inflamed tissues. She called at my office on the sixteenth day after the beginning of the trouble saying she was perfectly well.

Whether the infection was due to the abscess cavity or to the use of contaminated instruments in treating the diseased tooth I cannot say, but rather incline to the theory that it was originated by the abscess. I believe by the prompt removal of the tooth, thorough evacuation of the pus and irrigation of the cavity that a fatal issue was avoided.

In the further treatment of the case the cocain applications were abandoned after 6 or 8 hours, but the ice-bag was continued throughout the attack. The bowels were opened by the free use of salines. A liquid diet was necessarily used and alcoholic stimulants were freely administered.

THERMOL IN THE TREATMENT OF ENTERIC FEVER.

By R. D. RUDOLF, M.D.,

of Toronto, Canada.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN an article in your last issue Dr. A. B. Shimer, of Atlantic City, vaunts the value of the synthetic preparation called thermol in the treatment of typhoid fever.

I have never used the drug, and for aught I know it may be as good or even a better remedy in this disease than Dr. Shimer would have us believe. But where I would take issue

with him is in the fact that his evidence does not prove his case.

In the first place, the charts which he published to show the effect of the drug on the temperature are misleading in that the temperature is only recorded once in each day and no note of the hour is made.

A chart made from single daily records of the temperature will look quite different from one in which the morning and evening temperatures are taken. The latter one only will show the "typical typhoid temperature" which Dr. Shimer notes is absent in the charts given. In these charts the tracing is said in each case to begin in the first day of the disease, but evidently this is not the case, as Dr. Shimer himself states in the text that some of the cases had been ill for ten days before admission; in Case 4 the disease had already lasted for five weeks. The fever had therefore been running in every case given for many days, and I think that any hospital could produce charts of cases *not* treated by thermol in which the same gradual decline of fever occurred. The sudden rise occurring on the 9th (really the 19th) day of the disease in Case 5 and following a definite error in diet is in my experience not unusual, and the "prompt purgation with enemata removed this complication" in the words of Dr. Shimer. Hence is it not unfair for him to state later on that "the specific action of thermol is thus proven in Case 5, where a relapse was noted or, rather where an elevation of the temperature far beyond the normal temperature of that particular case was caused by the irritation of the food, thermol acted specifically in reducing the temperature"?

Dr. Shimer sets out by assuming that as "the most marked feature of typhoid fever is the fever . . . hence, in the treatment of a disease, the fever of which is the most marked symptom, especial attention should be given to the cause. The removal of the cause is not readily realized, and therefore the selection of some suitable antipyretic presents itself." I think that nowadays few physicians will agree with him that, with hydropathy available, typhoid fever should be systematically treated by any antipyretic, but even fewer will follow him when he recommends that "the mode of administration should be .80 grams at intervals of 2, 3, or even 4 hours, and to be given when the fever begins to rise, and to be continued *even after the fever has disappeared* in smaller doses and at longer intervals." (The italics are mine.)

So far, Dr. Shimer has noted no depressing effects from thermol, but if the drug is entirely free from such it must differ from every antipyretic which has so far been introduced.

It is with a sincere appreciation of the value of Dr. Shimer's work, and only in order that we may not be unduly biassed by any insufficiently supported conclusions that I thus venture to take up the pen of criticism.

Ovarian Carcinoma in an Eleven-year-old Girl.

—K. Walker (*Hygiea*, October, 1900) reports a case of carcinoma of the ovary occurring in a girl 11 years of age. The patient had had a brownish discharge from the genitalia for 7 months. For 2 months there had been a progressive enlargement of the abdomen whose circumference at the time of examination was 78 cm. at the umbilicus. Suspicion of pregnancy seemed justifiable, as by vaginal examination (two fingers could be easily introduced into the vagina) a growth was felt which gave the sign of ballottement, and in addition the breasts contained milk. Coitus was admitted. But as the uterus was of normal size and situated posteriorly, the diagnosis of carcinoma of the ovary was made. The existence of the tumor was confirmed by operation. Subsequent condition of the patient was good. [M.B.D.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. Melville D. Hayes, of Philadelphia, has been appointed assistant surgeon in the army, and has left for the Philippines to take up his duties.

The Samuel D. Gross Prize of \$1,000 will be awarded on October 1, 1901, no essay that was deemed worthy of the prize having been received on January 1, 1900.

College of Physicians.—Abstract of the monthly report of the Honorary Librarian, Library of the College of Physicians of Philadelphia, January, 1901. Books, pamphlets, and journals received: General Library, 464 volumes, 1,871 pamphlets, 6,040 journals; Lewis Library, 29 volumes; S. D. Gross Library, 5 volumes. Accessions, 290 volumes. Duplicates, 208 volumes. Donors, General Library, 63. The library received by the will of the late Dr. Alfred Stillé, 207 volumes of medical works and a copy of Sir Joshua Reynolds' portrait of John Hunter by Leslie.

Vital Statistics of Philadelphia for the week ended February 2, 1901:

Total mortality	552
CASES.	DEATHS.
Inflammation of appendix 4, brain 11, bronchi 13, kidneys 28, liver 2, lungs 96, peritoneum 5, pleura 3, stomach and bowels 24, bladder 2, heart 1, larynx 1, pericardium 1, veins 1, spine 1	193
Inanition 10, marasmus 7, debility 7	24
Tuberculosis of lungs	64
Apoplexy 16, paralysis 7	23
Heart—diseases of 36, fatty degeneration of 4, neuralgia 4	44
Uremia 6, diabetes 5, Bright's disease 11	22
Carcinoma of breast 4, face 1, stomach 2, uterus 5, jaw 1, colon 1, bladder 1, lungs 1	16
Convulsions	10
Diphtheria	79
Brain—softening of 4, congestion of 1, abscess of 1, disease of 1	7
Typhoid fever	47
Old age	19
Burns and scalds	2
Suicide	2
Alcoholism	1
Cyanosis	1
Scarlet fever	66
Abscess of liver	1
Influenza 19, abscess of pelvis 1, aneurysm aorta 1, asthma 4, anemia 3, abortion 1, casualties 11, congestion of the lungs 3, cirrhosis of the liver 4, cellulitis 1, tuberculosis of the bowels 1, membranous croup 4, diarrhea 2, disease of the spine 1, dropsy of the heart 1, epilepsy 1, erysipelas 2, catarrhal fever 1, malarial fever 1, puerperal fever 1, hemorrhage from lungs 1, hemorrhage from uterus 1, hernia 1, jaundice 1, locomotor ataxia 1, lymphadenoma 1, measles 1, obstruction of the bowels 3, edema of lungs 2, poisoning, carbolic acid 1, pyemia 1, rheumatism 1, sclerosis, arterial 3, shock, surgical 1, septicemia 7, sarcoma, liver 1, sarcoma, thigh 1, suffocation 1, tetanus 1, tumor, abdominal 1, ulceration of the bowels 1, unknown coroner case 1, whooping-cough 2	98

Academy of Surgery.—At the stated meeting of February 4, Dr. W. L. RODMAN read a paper on **The best incision for the removal of carcinoma of the breast.** The anatomy of the lymphatics of the breast was reviewed, this showing why cancer of the sternal quadrants is more fatal. The location of the growth and the age of the patient are the two most important prognostic elements. The younger the patient the less favorable is the prognosis. Of 3 cases under 30 years of age, 2 died in a short time of recurrence and the other bids fair to do the same. Dr. Rodman has a pathologist examine doubtful tumors by frozen section, as he does not remove the whole breast if the tumor be benign. In operating, the breast is detached from the sternum first, and then worked toward the axilla. The area of skin removed is large, as it is believed that more recurrences are due to the leaving behind of infected skin than to any other one cause.

Both pectoral muscles are removed only in tumors of the third degree—those which are adherent and immobile—but he is inclining more and more toward their removal in all cases, as the axillary glands can be reached more readily. The best incisions used for the operation are to a greater or less extent imitations of Halsted's. The essential features of a good incision are: 1. It is large enough to include all infected skin. 2. It exposes the pectoral muscles from origin to insertion. 3. It uncovers the axillary vessels and nerves. 4. It does not interfere with the future use of the arm. 5. No skin grafting is necessary. 6. The operation can be done in a reasonable length of time. The incision used by Warren is a valuable step in advance. By its use primary union can be secured after the removal of large tumors without skin grafting. Dr. Rodman has used it in 3 cases with good results. In one instance he modified it by making an additional curved incision above and toward the opposite breast, the case being one of recurrent growth and a large amount of tissue necessarily removed. The operation takes less time than by the Halsted method, an important point especially in elderly people. Patients are discharged in 10 to 12 days after the operation. In discussing the paper Dr. W. J. HEARN stated that in these cases he made a very long elliptical incision which extends from the insertion of the pectoral muscle to the costal margin. The boundaries are dissected well back for flaps. The fat beneath the pectoral muscles is then removed, which exposes the small tributary bloodvessels which pass downward. These vessels are ligated before they are cut. The pectoralis major is always removed, the minor not in all cases. The edges of the wound can nearly always be brought together, one straight line of sutures being formed. Dr. JOHN B. ROBERTS always begins above the clavicle, the flap being turned toward the mid line in order to avoid sloughing of the point of the flap, which is apt to occur in the Halsted method. The infra-clavicular glands are then removed. Both muscles should be removed in every case. Dr. RODMAN stated that the belief that cancer was rare in the colored race was passing away. He finds the disease fully as often in colored people as in whites.

Dr. W. J. HEARN exhibited a case of **pneumotomy for gangrene of the lung.** Several operations had been done and the wound drained for 2 years. At the last operation the walls of the abscess cavity were stitched to the skin. A plastic operation later on will close the large external opening which now exists.

Dr. DEFOREST WILLARD reported a case of **traumatic aneurysm of the thoracic aorta** which has been treated by the insertion of wire. Twenty feet of silver wire was introduced and an 80 milliampere galvanic current passed for 60 minutes. The patient is now doing well and the pulsation has decreased at least 25%. Dr. D. D. STEWART spoke of the technic of the operation. He first introduces a cannulated needle to find the thinnest place in the wall. In some instances 4 punctures have thus been made, this being done several days before the wire is introduced. Gold wire is used, as it can be more finely drawn, 28 to 30 gauge being employed. Not more than 15 feet is introduced and this is better done through several needles, thus reaching all parts of the sac. The positive pole is applied to the wire and a current of 80 to 100 milliamperes passed for 30 minutes. One-fourth grain of morphia is given before the operation and if the heart's action is high aconite is given for a few days before. Morphia is also given during the operation if the patient be apprehensive and excited.

NEW YORK.

Dr. F. W. Barrow, professor of histology and biology at Buffalo University Medical College, was elected president of the New York State Association of Science Teachers.

Dr. Seymour Oppenheimer has been appointed consulting otologist and laryngologist to the Hebrew Sheltering Guardian Society of New York.

University of Buffalo.—The Medical Department of the University of Buffalo is in receipt of a gift of \$50,000 for the purpose of erecting a laboratory to be devoted entirely to research work. It will be known as the Gratwick Research Laboratory.

Marine Hospital.—A recommendation has been sent to Congress by Secretary Gage that \$100,000 be immediately made available for the purpose of reclaiming certain plots of land in New York harbor as a site for a Marine Hospital.

Hospital for Dobbs Ferry.—The Dobbs Ferry Hospital Association is to erect a hospital on Ashford Avenue. The plans are to be ready March 1, and the building begun by May 1. The building will be large enough to contain 3 private rooms and 2 wards containing 6 beds each.

New York Academy of Medicine.—The report of the Library Committee of the New York Academy of Medicine shows that they had, November 30, 89,000 volumes, including 36,105 duplicates. The library is growing at the rate of more than 3,500 volumes a year. The number of journals on file is 941.

Manhattan Dermatological Society.—A regular meeting was held at the residence of Dr. E. L. Cocks, No. 156 W. 119 Street, on Friday evening, February 1, with Dr. WM. S. GOTTHEIL as presiding officer.

Dr. B. F. OCHS presented 3 cases of scabies in a father and 2 sons. One boy showed a severe impetigo contagiosa, the other a beginning furunculosis and the father an incipient beginning of the disease. Drs. OBERNDORFER and GOTTHEIL took exception to the use of the term impetigo contagiosa except as a distinct disease. Drs. COCKS and SOBEL spoke very highly of Sherwell's powdered sulphur treatment. Dr. WEISS said that the first case resembled Norwegian scabies or scabies gigantica. Dr. Gottheil presented for opinions as to treatment, extensive keloidal hypertrophic growths of the face and elbow, following a severe burn. Dr. GEYSER recommended covering the false keloids with cloths moistened in a saturated solution of magnesium sulfate and then passing the negative galvanic electrode through this, for from 10 to 20 minutes, 3 times weekly. Dr. SOBEL has had very fair results from the passage of the negative galvanic needle through the outlying dilated capillaries. Dr. OCHS has used oleate of mercury with no result. Dr. ABRAHAM said that injections of 95% alcohol had lately been recommended. The general opinion was that thiosinamine was useless. Dr. Gottheil advocated linear scarification and cross-hatching followed by mercurial plaster.

Dr. GOTTHEIL presented a relapsing vesicular and erythematous eruption of the leg, which he first treated as an eczema, but which he now considers dermatitis herpetiformis. Dr. KINCH excluded eczema on account of the sharp border and marked pigmentation. Dr. WEISS considered it eczema vegetans, Dr. COCKS vesicular eczema, Dr. ABRAHAM pemphigus vulgaris, Dr. OCHS dermatitis herpetiformis, and Dr. OBERNDORFER an eczema modified by a "run down" condition.

Dr. L. G. COCKS presented a case of acne varioliformis cured by curettage and white precipitate ointment—a prominent dermatologist had diagnosed syphilis from the appearance of the scars. Dr. OBERNDORFER remarked that the scars of acne varioliformis were minute and that white precipitate effected a cure in both this condition and syphilis. Dr. SOBEL agreed that the scars of acne varioliformis were as a rule very small, but would hesitate to diagnose a condition from the scars alone. Unguentum hydrargyri ammoniat. was the remedy par excellence and must be used even after apparent cure. Dr. OCHS thought that the scars might have been enlarged by the curet. Dr. WEISS had seen large scars from acne varioliformis and thinks it risky to make a diagnosis from the scars. Dr. GOTTHEIL considers it a syphilide.

Dr. E. L. COCKS presented a case of lupus vulgaris of the forehead and nose, and a case which presented features of both a psoriasis and seborrheal eczema.

Dr. GOTTHEIL presented a patient with a fine desquamation of the face following a scarlatiniform eruption of three weeks ago. The same patient showed a marked keratosis palmaris et plantaris of one week's duration. Drs. WEISS and OBERNDORFER considered the face eruption as due to a coal-tar product. Dr. SOBEL said that the patient admitted having used quinin and he would look upon this as a scarlatiniform erythema due to this drug. Dr. FRANKLIN remarked that the hands were suggestive of acid burns. Dr. GOTTHEIL in closing said that the keratosis was surprisingly acute.

NEW ENGLAND.

Appointments.—Drs. A. G. Nadler, J. J. Cohane, F. A. Kirby, P. D. Littlejohn, and E. P. Pitman have accepted appointments as school inspectors of New Haven.—The National Society for the Study of Epilepsy has appointed Drs. Max Mailhouse, of New Haven; F. K. Hallock, of Cromwell, and E. A. Down, of Hartford, a committee to collect data regarding the malady and to instigate a movement in this State for establishing an asylum for such cases.

CHICAGO AND WESTERN STATES.

Acute contagious conjunctivitis is reported to be epidemic in Chicago.

Ohio State Medical Society.—The Ohio State Medical Society will meet in Cincinnati May 8, 9, and 10.

Dr. Charles Osborne, Coroner of Clinton County, Iowa, and a most promising young physician, died, February 3, at St. Joseph Hospital, Dubuque.

Dr. Charles D. Aaron, of Detroit, Mich., has been elected clinical professor of diseases of the stomach and intestines in the Detroit College of Medicine.

American Medico-Psychological Association.—The next annual meeting of the American Medico-Psychological Association will be held in Milwaukee, Wis., June 11, 12, 13, and 14, 1901.

Smallpox.—Out of 114 counties in the State of Missouri, 96 report smallpox.—During the year 1900 there occurred in the State of Ohio 2,696 cases of smallpox. The disease appeared in 172 communities in 62 counties.

Marriage Laws.—A bill has been introduced in the Minnesota Legislature by Dr. E. V. Chilton, of Howard Lake, which provides that a marriage shall not be allowed between two persons where either one is or has been subject to fits of any kind, insanity, or any loathsome disease. The bill further provides that a certificate of a physician, showing that the applicants are fit to enter the married state, shall accompany all applications for a marriage license. This Act places the age limit for women at 45 years, but no provision is made for men as regards age. The penalty for a violation of the law is a fine of \$1000 or 5 years in the penitentiary, or both, and applies to the persons who marry as well as the clergyman or justice performing the ceremony.

A Medical Protective Association.—There has been organized at Fort Wayne, Ind., an association known as the "Physicians' Guarantee Company." The object of this association is to defend any physician or surgeon sued for malpractice. It is organized with a capital of \$100,000, and has a reserve fund of \$50,000, and its officers are men well and favorably known for many years—men like Drs. A. P. Buchman and Miles F. Porter, for a long time teachers in the Fort Wayne College of Medicine. It was incorporated under a peculiar statute of Indiana, which provides for associations "for the purpose of aiding, indemnifying, and protecting the medical profession in scientific researches, and in the practice of medicine and surgery"—a statute totally different from that found in any other State, and amply covering all requirements of the company to operate in every State.

SOUTHERN STATES.

Dr. Fairfax Schley, of Frederick, has been elected president of the visitors' board of the Maryland School for the Deaf, located in that city.

Successful Cesarean Section.—Dr. George B. Johnston, of Richmond, Va., reports a successful case of cesarean section. Patient had a contracted pelvis.

Society for the Study of Tuberculosis.—A society for the study of tuberculosis, which takes its name from Laennec, the discoverer of auscultation as a means of physical diagnosis, has been organized in connection with Johns Hopkins Hospital, Baltimore.

Appointed by Commissioners.—Dr. Herbert N. Manning has been appointed by the District Commissioners resident interne at the Washington Asylum Hospital, vice Dr. Melville A. Hays, resigned.

Dr. Wm. D. Haggard, Jr., of Nashville, has been elected to fill the chair of gynecology and diseases of children in the medical department of the University of Tennessee, formerly occupied by his father.

Medical Staff for the Home for Friendless Women.—The following medical staff was elected in January by the managers of the Home for Friendless Women, at Louisville, Ky.: Dr. Ewing Marshall, chairman; Dr. Henry E. Tuley, secretary; Dr. W. F. Bogges, Dr. P. F. Barbour; Dr. Lindsey Ireland, vice Dr. F. C. Simpson resigned; Dr. Hugh N. Leavell, vice Dr. Louis Frank resigned.

Dr. Paul Jencke, a prominent physician of Linn, Mo., died January 30, 1901. He was born in Dresden, and was a graduate of the University of Leipzig. He came to the United States about 1876, and attended the Missouri Medical College in St. Louis, where he graduated two years later. The doctor came from a prominent family in Germany. His father, who died some two years since, was Court Councillor.

New Orleans Parish Medical Society.—The following officers were elected: Dr. E. Martin, president; Dr. H. B. Gessner, first vice-president; Dr. L. G. LeBeuf, second vice-president; Dr. Geo. Stumpf, third vice-president; Dr. W. M. Perkins, recording secretary; Dr. M. H. McGuire, treasurer; Dr. S. P. Delaup, librarian and corresponding secretary; additional members to complete board of directors: Drs. John Callan, H. D. Bruns and T. S. Dabney.

MISCELLANY.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended February 2, 1901:

SMALLPOX—UNITED STATES.

Quarantining Tuberculosis.—Tuberculosis has been placed among the diseases which are subject to quarantine. The commissioner of immigration has so decided in the case of a Japanese who arrived in San Francisco from Japan, ill with lung trouble. It was decided that the patient could not land, but must return to the port from which he sailed.

The Omega Upsilon Phi Fraternity (medical) has just organized two new chapters, one at the University of Colorado, composed of 15 students and several members of the faculty; the other, a graduate chapter in New York City, to be known as the "Henry C. Coe Chapter," in honor of Professor Coe of the University and Bellevue Hospital Medical College.

Obituary.—DR. HOMER OCTAVIUS JEWETT, at Cortland County, N. Y., on January 30, 1901, aged 82 years.—DR. THEODORE DECLERMONT MILLER, at New York, on January 28, 1901, aged 59 years.—DR. JOSEPH ERNALES MUSE CHAMBERLAINE, of Easton, Pa., on January 30, 1891, aged 75 years.—DR. A. J. NORRIS, of Macon, Mo., on January 28, 1901, aged 56 years.—DR. MICHAEL ROYSTON FIGOTT, at Annapolis, Md., on January 31, 1901, aged 35 years.—DR. WESLEY W. BARKWELL, at Tucson Ari., on January 28, 1901.—DR. HENRY W. TAYLOR, at Sullivan, Ind., on January 30, 1901, aged 59 years.—DR. JOSEPH SEMSCH, at La Crosse, Wis., on January 30, 1901, aged 87 years.—DR. HENRY F. BAXTER, at Philadelphia, Pa., on February 1, 1901, aged 58 years.—DR. ROSIER MIDDLETON, at Washington, D. C., on January 31, 1901.—DR. L. H. JONES, of Yazoo City, Miss., at Jackson, Miss., on January 29, 1901.

Changes in the Medical Corps of the U. S. Army, for the week ended February 2, 1901:

NEWLOVE, GEORGE, acting assistant surgeon, is assigned to duty at Fort Sill until further orders.

BARNEY, CHARLES NORTON, acting assistant surgeon, is granted leave of absence for 1 month.

HESS, First Lieutenant LOUIS T., assistant surgeon, now on duty at the Army General Hospital, Presidio, is relieved from further duty in the division of the Philippines.

STOCKARD, JAMES K., acting assistant surgeon, now in San Francisco, Cal., will report to the commanding general, department of California, for assignment to temporary duty in that department.

LECOMPTÉ, WILLIAM C., acting assistant surgeon, having reported to the Surgeon-General of the Army, will proceed to Fort Du Pont.

WILLIAMS, ADRIAN D., acting assistant surgeon, will proceed from Brooklyn, N. Y., to Fort Adams for temporary duty.

BELL, JOSEPH L., acting assistant surgeon, will proceed from Richmond, Ind., to Omaha, Neb., and report to the commanding general, department of the Missouri, for assignment to duty at Fort Crook.

HICKSON, JOSEPH H., hospital steward (appointed January 25), now at the Army General Hospital, Presidio, will report to the commanding general, department of California, San Francisco, Cal., for assignment to duty.

MULLINS, THOMAS K., acting assistant surgeon, is granted leave of absence for 1 month, without pay, to take effect upon the expiration of the leave granted him January 8.

BISPHAM, First Lieutenant WILLIAM N., assistant surgeon, is relieved from duty at Columbia Barracks, Cuba, and will report at Cabana Barracks, Cuba, for duty as surgeon, relieving Acting Assistant Surgeon H. M. James.

MAZZURI, PAUL, acting assistant surgeon, is relieved from duty at Cabana Barracks, Cuba, and will report at Columbia Barracks, Cuba, for duty.

WARREN, STANLEY S., acting assistant surgeon, now on duty at Fort Clark, will proceed to Fort Sam Houston, and upon arrival report to the commanding officer for duty during the absence of Acting Assistant Surgeon James S. Kennedy.

KENNEDY, JAMES S., acting assistant surgeon, is granted leave of absence for 20 days, to take effect January 21.

POLHEMUS, Captain ADRIAN S., assistant surgeon, now on duty at Fort Leavenworth, will proceed to Fort Riley for temporary duty at that post during the absence of Captain Charles E. Woodruff, assistant surgeon.

DE WITT, Lieutenant-Colonel CALVIN, deputy surgeon-general, is granted leave of absence, on surgeon's certificate, for 3 months from about February 10.

MCCALLUM, F. M., acting assistant surgeon, will proceed from Jefferson Barracks to Fort Reno for temporary duty.

Changes in the Medical Corps of the U. S. Navy,
for the week ended February 2, 1901:

McCLURG, W. A., medical inspector, commissioned medical inspector, November 19, 1900.
SHIFFERT, H. O., assistant surgeon, ordered to the "Franklin."
GROW, E. J., assistant surgeon, detached from the "Culgoa" and ordered to the "Glacier," and also to duty at Olongapo, P. I.
COWEN, J., pharmacist, detached from the "Culgoa" and ordered to the "Glacier," and also to duty at the Naval Hospital, Cavite, P. I.
PIGOTT, M. R., passed assistant surgeon, died at Annapolis, Md., January 31, 1901.

Changes in the U. S. Marine-Hospital Service,
for the week ended January 31, 1901:

McINTOSH, W. P., surgeon, to proceed to Jeffersonville, Ga., for special temporary duty. January 30.
PERRY, T. B., surgeon, granted leave of absence for 30 days from February 11. January 30.
McMULLEN, JOHN, assistant surgeon, upon expiration of leave of absence, to proceed to Wilmington, N. C., and assume temporary command of the service during the absence of Surgeon T. B. Perry. January 30.
CORPUT, G. M., assistant surgeon, to proceed to Cleveland, Ohio, and assume temporary command of the service during the absence of Surgeon W. J. Pettus. January 26.

BOARD CONVENED.

Board convened to meet at Washington, D. C., on Tuesday, February 5, 1901, for the physical examination of Second Assistant Engineer R. F. HALPIN, R. C. S. Detail for the board—Surgeon PRESTON H. BAILHACHE, chairman; Surgeon G. T. VAUGHAN, and Assistant Surgeon B. S. WARREN, recorder.

Foreign News and Notes.

GREAT BRITAIN.

Dr. T. C. Vachell has withdrawn his resignation as physician to the Cardiff Infirmary.

Miss M. M. T. Christie, M.D. Lond., has been appointed to the permanent charge of the Victoria Dufferin Hospital in Calcutta.

Smallpox at Glasgow.—Smallpox is reported to be increasing at Glasgow to an alarming extent. Twenty-nine new cases are reported and hundreds of cases are being treated in the hospitals.

Elections.—**Mr. W. H. Willcox, M.B., B. Sc. Lond., D.P.H., A.T.C.,** has been elected to the post of lecturer on chemistry and physics at St. Mary's Hospital Medical School, London. **Sir James Sawyer, M.D.,** has been elected a Fellow of the Society of Antiquaries.

Investigating Beer-poisoning.—The *Lancet* says: A Royal Commission has been appointed to make investigations respecting the beer poisoning epidemic. The Commissioners are Lord Kelvin, Sir W. Hart Dyke, Sir W. S. Church (President of the Royal College of Physicians of London), Professor T. E. Thorpe (Government Analyst), Mr. H. Cosmo Bonsor, and Dr. B. A. Whitelegge (H. M. Chief Inspector of Factories). Dr. G. S. Buchanan, one of the medical inspectors of the Local Government Board, is the secretary of the commission. The instructions to the commissioners are to ascertain with regard to England and Wales: 1. The amount of recent exceptional sickness and death attributable to poisoning by arsenic. 2. Whether such exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, and, if so, (a) to what extent; (b) by what ingredients or in what manner the arsenic was conveyed; and (c) in what way any such ingredients became arsenicated. 3. If it is found that exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, by what safeguards the introduction of arsenic therein can be prevented.

CONTINENTAL EUROPE.

The Medical Profession of Germany has sanctioned the imperial bill lengthening medical study to at least five years.

Kleines Journal f. Hygiene.—A special supplement to the German magazine, the *Kleines Journal*, is to be published by a medical editor, with the title of the *Kleines Journal f. Hygiene*.

School for Tropical Diseases.—It has been decided by the Faculté de Médecine of Paris to establish a school for the study of tropical diseases, with special chairs of bacteriology and parasitology.

Royal Personages Contract Measles.—The Duke Regent of Mecklenburg-Schwerin and the Duchess, who is a daughter of the late Grand Duke, are down with the measles, as is also the young Grand Duke of Saxe-Weimar.

Appointments.—DORPAT, Russia: Dr. Yewetsky, professor of the medical faculty of Moscow, has been appointed professor of ophthalmology at Dorpat, succeeding Professor Rählmann.—FREIBURG: Dr. Adolf Schüle has been appointed professor of internal medicine.

MISCELLANY.

Obituary.—**DR. DUBRUEIL**, former professor of the surgical clinic at Montpellier, France.—**DR. DUCLOS**, former professor of the Medical Clinic at Tours.—**PROFESSOR PODREZE**, of Charkow, an eminent Russian surgeon.

The St. John's Ambulance Association attended 1,805 persons injured during the funeral crushes in London. The association has 701 doctors and nurses busy at 26 stations. Prior to the arrival of the funeral train, Major Edward Bassindale, a veteran officer, fell dead in the crowd, as the result of excitement. There was a crush in the crowd at the Marble Arch, when the gates were unexpectedly closed after the procession had passed.

A Modification in Ophthalmic Test-Types.—The *Lancet* states that Dr. E. Praun, of Darmstadt, has proposed an ingenious substitute for the types generally in use for the purpose of testing the sight. He observed that some school children and also a railway engine-driver whom he had occasion to examine succeeded in learning the ordinary test-types by heart, so that they could name the letters without being able to see them distinctly, and thereby made their vision appear to be better than it really was. In order to counteract this artifice Dr. Praun suggests that the use of letters of the alphabet as test-types should be discontinued and substitutes for them two thick parallel black lines of unequal length joined together by their ends, some of them at an angle of 45° and others at a right angle forming L. These radiating pairs of lines he regards as the hands of a clock, and his sheet of test-types consists of 47 such pairs of lines of different sizes placed within circles, arranged in two squares of 9 and 36 figures respectively and 2 separate figures. Each of these squares is mounted on cardboard and rotated into different positions, so that the most retentive memory would be unable to remember all the possible combinations and the reality of the test would be assured.

The Teaching of Colonial Medicine.—**Dr. Boinet**, Professor of Tropical Diseases (*Gazette Medicale de Paris*, January 5, 1901), explains in his opening lecture the purpose of the School of Tropical Medicine recently established in Marseilles. He expects to be able to study scientifically numerous tropical diseases which are as yet obscure; he hopes that men who have returned from the Colonies, poor and ill, undermined by fever or dysentery, will receive aid here; he believes that students who expect to practise in tropical countries will learn to diagnose and treat the affections most commonly found there. This refers especially to those intending to enter the Army, the Marine, or Colonial Service. He thinks that all who are destined to fill civil posts in the tropics,—government officials, missionaries, etc., will here be given the chance to learn what to do, should no physician be within call. He relates his own experience in Tonkin, in 1887, when he had 31 grains of quinin hypodermically, and 62 grains by the mouth, believing that these large doses, given him by his colleagues, alone saved his life. Besides, the cases which he expects will be sent to Marseilles, such as dysentery, abscess of the liver, malaria, and leprosy, are, or were, endemic in the south of France. While England already has three Schools of Tropical Medicine, this is the first one opened in France. [M.O.]

1. A Clinical Lecture on Malignant Diseases of the Female Genitalia. THOMAS OLIVER.
2. A Clinical Lecture on Diagnosis in Cancer of the Body of the Womb. W. HANDFIELD JONES.
3. Spoon-shaped Indentations in the Skulls of the Newborn. J. M. MUNRO KERR.
4. Impacted and Displaced Gravid Uterus with Fibroid. NEIL MACLEOD.
5. A Second Successful Case of Cesarean Hysterectomy. COLIN CAMPBELL.
6. A Note on the Treatment of Puerperal Eclampsia. R. P. RANKEN LYLE.
7. A Note on the Occurrence of Abortion. J. B. HELLIER.

1.—Oliver includes under the term **malignant diseases of the female genitalia** such affections as cancer, sarcoma, malignant adenoma, and deciduoma malignum. It is characteristic of them all that they tend to pass beyond the organ in which they originate and to invade other organs or tissues. He especially dwells upon malignant diseases of the womb. Carcinomata originate under the flattened epithelium which lines the vaginal face of the cervix or in the columnar epithelial cells of the tubular glands of the cervical canal. When the disease is present in the exposed part of the cervix it has usually originated beneath the flattened epithelium and tends to burrow. When the disease originates in the cells of the cervical mucous membrane, or in those of the tubular glands of the cervix, the ciliated epithelium loses its cilia, and there follows marked proliferation of the cells, whereby the structure comes to resemble exuberant gland-tissue. In cancer of the body of the uterus the disease arises either in the ordinary epithelial cells that line the endometrium, or in those of the tubular glands. It is when the disease originates in the glandular structures that it gives rise to what is known as adenoma malignum. The cause of cancer is still unknown. It is certainly a local disease at first, as is shown by the success which follows early extirpation. The treatment of malignant disease of the uterus varies according as to whether the cases are inoperable or those that are suitable for operation. Oliver has not seen any benefit follow from the internal administration and local application of arsenic, nor has thyroid extract done any good. The cases suitable for operation are those in which the disease is limited to a very small part of the cervix, or, when located in the uterus itself; the womb while involved is freely movable. [W.A.N.D.]

2.—Handfield-Jones from his study of **cancer of the body of the womb** believes that the following conclusions probably represent the sum of our knowledge at the present time: (1) That in cases of corporeal cancer there is a stage of benign adenoma; (2) Uterine scrapings are not perfectly reliable, owing to the tissue being only superficial, and the deep part of the gland not being obtained. Later scrapings, when the disease is more advanced, are more reliable; (3) clinical signs are more reliable than microscopic evidence; (4) The degree of malignancy varies much, and the disease may run a very slow course; (5) rapid increase in the size of the body of the womb is the most valuable sign in determining need for extirpation of the whole organ. [W.A.N.D.]

3.—Kerr remarks that **indentations of the fetal skull** may be either spoon or furrow-shaped. The 2 varieties occur with about equal frequency. They have not, however, the same significance, for although the conditions producing them are in the main the same, the furrow-shaped variety is much the less serious and seldom gives rise to much immediate trouble. The spoon-shaped injury, which is situated usually on one or other parietal or frontal bones in the neighborhood of the anterior fontanel, is by no means uncommon. With few exceptions the accident occurs when there is a deformity of the maternal pelvis, and as rickets is the most common cause for such deformity the injury is generally met with in the offspring of women with flat, rachitic pelvises. Generally speaking the prognosis is not unfavorable. If the children are born alive the indentation, in the majority

of cases, disappears in a week or two, having given rise to no trouble at the time, and producing no ill effects later. In a certain number of cases, however, the depressions are deeper and produce a permanent deformity. Abfield mentions 10 cases with 2 deaths. Kerr has seen 4 cases with 2 deaths. As regards treatment, Kerr remarks that a very little force applied to the depression from the inside is all that is necessary to relieve the indentation. The force must be applied early, otherwise there may occasionally be a little difficulty in raising the bones. This force may be secured by making firm compression of the head anteroposteriorly, thereby causing the depressed bone to spring out. While successful in a few cases this method is not always applicable. [W.A.N.D.]

4.—Macleod reports an interesting case of **impacted and displaced gravid uterus** at term complicated by fibroid tumor, in which cesarean section was performed together with excision of the fibroid tumor and of the entire anterior uterine wall. The patient made an uninterrupted recovery. [W.A.N.D.]

5.—Campbell recalls a successful case of **cesarean hysterectomy** in a dwarf four feet in height. The operation was performed under the most unfavorable conditions, but the patient made a complete recovery. [W.A.N.D.]

6.—Lyle remarks that there are three great principles in the **treatment of puerperal eclampsia**, namely, purification of the blood, the control of convulsions, and the emptying of the uterus. Dietetic infusion is a valuable addition to the usual treatment adopted for purifying the blood, but it has no immediate effect in controlling the convulsions, nor has it any effect on the action of the uterine muscles. He prefers morphin, judiciously given, to control the eclamptic seizures. [W.A.N.D.]

8. Infective Parotitis after Abdominal Section. WM. ELDER.
9. A Case of Gangrene of the Penis. GEORGE A. CLARKSON.
10. Reflections on Therapeutics. HARRY CAMPBELL.

1.—Freyer thinks that in certain selected cases some form of operative treatment may be recommended; in a few cases it is imperative, but that in the large majority of cases clean catheterization and a hygienic life is the best treatment. When no symptoms are present no treatment is required. If symptoms of obstruction are present and the amount of residual urine small, he uses ergot and the weekly introduction of a bougie as far as the bladder. When the residual urine reaches 4 ounces the catheter should be used once a day; 6 ounces, twice a day; 8 to 10 ounces, three or four times a day. When all voluntary power is lost the catheter should be used as often as the desire is markedly felt. Patient should not be limited to a certain hour, but, on the contrary, should use the catheter before pain and marked discomfort are felt. The choice of catheter will depend on the form of obstruction—patient should never be without one. Usually a soft Condé's, No. 7 or 9, is most useful. Patient should not be allowed to use a metal catheter. The aseptic precautions necessary in the use of the catheter are gone into carefully. The hygiene of the patient should be carefully looked after; the diet, the clothing, the bowels, etc. Horseback and bicycle riding are to be avoided, as is also sexual excitement. Under proper care many patients are

able to lead "useful and enjoyable lives for 15 or 20 years,"—"after entering on the habitual use of the catheter." In far advanced cases when urine is turbid or fetid the patient should be examined in his own bed and only a portion of the residual urine withdrawn at the first examination. It is not right to examine such a case and allow him to go out of doors immediately afterward; he should remain in bed. **Urethral fever** from catheterization is apt to follow in these cases. **Cystitis** is a common complication. In the beginning boric acid should be employed, and Freyer has found that several large doses (25 grains) are better than small doses frequently repeated. When pus is present irrigation daily with some warm and mild antiseptic is employed. Silver nitrate begun in solution of 1:4000 and gradually increased to 1:750 is highly recommended. For the great pain and scalding at the neck of the bladder a dram of a 1% to 3% solution of silver nitrate thrown into the membranous urethra is of great advantage. **Complete retention** of urine should be relieved by catheter, aspiration, or drainage as soon as possible lest an atony of the bladder result. The preprostatic pouch is frequently overlooked and mistaken for the bladder cavity itself. It is the dilated prostatic urethra and bladder in front of the enlarged middle lobe. Freyer has frequently seen the pouch emptied by the catheter and the attendant think he had emptied the bladder. He has several times removed stones from this position. **Hemorrhage** is liable to take place in the advanced cases, but is not apt to be serious unless due to a ruptured varicose vessel in the gland. Rest in bed is the most important part of the treatment. Frequent hemorrhage after exercise should suggest stone. Orchitis, urethritis, and balanitis not infrequently occur as complications, the latter two particularly in patients suffering from diabetes. **Operative treatment:** Freyer describes the various operations for the removal of the enlarged portions of the prostate and recommends for enlargement of the middle lobe the suprapubic operation of McGill; for enlargement of the lateral lobes an operation of his own consisting of a preliminary incision through the urethra and then Dittel's incision through the perineum. The wound in the urethra allows the introduction of the finger into the bladder, a thorough examination of the gland and its easy protrusion by the finger into the perineal incision, and a means of thorough drainage afterwards. It also serves the important purpose of protecting the bladder from injury, as the finger can appreciate the approach of the cutting instrument. **Castration** with its very satisfactory results in some cases and its objectionable features to the patient is carefully discussed. The mortality in the far advanced cases, the only ones where the operation is acceptable, is the greatest objection to the operation. Both of these objections are overcome in the operation of **vasectomy**, but the results are hardly as satisfactory. This operation successfully prevents the distressing complications of orchitis and epididymitis which so frequently occur in prostatic patients. In the hard fibroid form of enlargement the operation was little or no good. Although preventing the expulsion of semen vasectomy does not interfere with the sexual power. **Drainage**, as a palliative measure, should be obtained through the perineum when it is required temporarily and when the patient is much enfeebled. For permanent drainage the suprapubic route is the best. [J.H.G.]

2.—Page in a clinical lecture on **head injuries** urges the close observation of all symptoms in such cases. He first speaks of a case sent to the hospital as concussion and as needing operation, in which it was subsequently found that the patient was suffering from embolism. The case first shown is that of a boy admitted to the hospital suffering from an extensive fracture of the upper occipital region. He exhibits perimeter charts showing complete and absolute homonymous hemianopsia soon after the injury, and later charts showing nearly complete restoration of vision. The second case shown was that of a boy 14 years of age admitted in a dazed condition with a large hematoma over the right frontotemporal region. The eyelids were swollen and completely closed. There were no unilateral phenomena. When examined the next day there seemed to be a depression of the bone beneath the hematoma and an exploratory incision was made, which showed that the sense of depression was due to a well marked temporal ridge, and that no fracture of the skull was present. The next case is that of a man, 29

years of age, admitted in profound unconsciousness with relaxation of sphincters and slight bleeding from the right ear, which soon ceased and was not succeeded by the escape of cerebrospinal fluid. There was considerable bruising on the side of the head, but no unilateral symptoms. The patient recovered slowly but complained of great pain in his head. The presence of slight facial palsy seemed to confirm the impression that there had been a fracture of the base, but this was subsequently explained by the patient who said it was of long duration. Page thinks in the majority of cases of severe concussion that there has been more or less laceration of brain tissue and very commonly an extravasation of blood into the arachnoid cavity. He urges that in all injuries to the head adequate rest must be given to the brain and the patient not discharged from the hospital too early. [J.H.G.]

3.—Sinclair reports 10 cases of successful cesarean section performed during the past 10 years. In 3 of the cases the uterus was removed. In these cases no sugar was subsequently found in the urine, and the milk did not appear in the breasts. In 2 of the cases previous craniotomy had been performed. In discussing these cases Sinclair says that previous to and during the operation the fewer manipulations of the uterus, especially per vaginam, the better, and that he sees no advantage in the previous dilation of the cervix. In all of his operations the uterus was brought through the abdominal incision before it was opened and an elastic tube was placed about the cervix for the control of hemorrhage. Rupture of the membranes reduces the size of the uterus and renders the operation easier. He does not think that the elastic ligature produces atony of the uterus. He thinks that an incision $4\frac{1}{2}$ to 5 inches long in the uterus is necessary for safe delivery. The transverse incision across the fundus of the uterus is condemned because of the likelihood of subsequent adhesion of the bowel or the abdominal wall, which seriously complicates future pregnancies. He always makes the median incision in the middle third of the uterus. In his recent cases drainage has been abandoned. [J.H.G.]

4.—Reynolds gives an account of the epidemic outbreak of **arsenical poisoning** occurring in beer-drinkers in the north of England and the Midland counties in 1900. During the year a number of patients presented themselves showing various skin eruptions, such as erythema, keratosis, pigmentation and herpes zoster. These skin lesions occurred in association with alcoholic paralyses. For some time Reynolds was at a loss to explain why neuritis occurred only in beer-drinkers and not in spirit-drinkers. In many of the cases the skin lesions associated were herpes. He concluded therefore, that as arsenic was the only known drug to produce herpes, this was the cause of the epidemic. On November 18, 1900, some of the beer commonly partaken of by one of the sufferers was examined for arsenic with a positive result. The arsenic in the beer was traced to a number of sources, the most important origin was in certain sugars used in brewing. A single firm supplied 200 breweries with sugar which contained arsenic. The poison gained entrance through the sulphuric acid used in converting starch into sugar. The original source of the arsenic was found in the Spanish pyrites used in the manufacture of sulphuric acid. A quantitative estimation showed that there was from .14 of a grain to .3 of a grain of arsenic in a gallon of beer. Another way by which arsenic may gain entrance is through sulphureted hops. He reports a case of poisoning due to the chewing of hops. In the cleansing of the barrels and the "fining" of the beer calcium bisulfate and sulphuric acid were used. He cites still another way in which arsenic may gain entrance, namely, through certain microorganisms which have the power of taking up substances and liberating poisonous arsenical compounds. The epidemic principally involved those districts which were supplied with contaminated sugar. The number of individuals poisoned and the number of deaths could not be accurately ascertained. In Manchester alone 2,000 cases were reported. In discussing the symptoms he lays stress upon the fact that the diagnosis is very easy in typical cases. The patient complains of pain in the extremities, often shooting in character, headache, lachrymation, cough, shortness of breath, and diarrhea. In many instances the patient has a characteristic "double-rap" gait, the heel first touching and then the anterior portion of the foot. Rashes, edema of the face

and extremities, pallor and some cyanosis may be striking signs. The skin lesions are numerous and present in almost every case. They were: Erythromelalgia, keratosis, erythema, often accompanied by great itching; pigmentation, simulating that of Addison's disease, and herpes zoster. Loss of hair occurred in some cases. The nails were thin and brittle, and it appeared that some time after the patient discontinued taking the beer the new-formed portion of the nail could be distinguished from the diseased part by a distinct ridge. In a few cases successive weekly drinking bouts seemed to produce a series of ridges across the nails. Symptoms referable to the nervous system were numerous. Sensory affections were present in every case, varying from slight paresthesia to total loss of sensation, neuralgias and tenderness over the muscles. In one case the sensory portion of the left fifth cranial nerve was partially paralyzed while the motor portion was not involved. Motor symptoms were present in about 70% of the cases. Loss of power was especially prominent in the lower extremities, showing itself in the gait and in some instances there was complete loss of power. The hands and forearms were also involved in many cases. Early in the course of the disease the knee-jerks were often exaggerated. Late in the course of the disease, when paralysis and atrophy became prominent, the knee-jerks were absent. In a few cases confusional insanity developed. Signs of cardiac dilation were present in a majority of the cases. Heart failure was the chief cause of death in the greater number of fatal cases. Edema was often present. The chief symptoms referable to the respiratory tract were bronchitis, hemoptysis and congestion of the fauces, and of the vocal cords. In a few instances of latent phthisis, rapid breaking down of the lung tissue occurred with the arsenical poisoning. In the early stages of the poisoning the appetite was increased, while in the later stages it became impaired. Some patients complained of vomiting and of diarrhea, with the passage of blood in the stools. Reynolds states that he believes that arsenic may set up chronic interstitial hepatitis. He found arsenic in the urine of patients who had recently partaken of arsenicated beer. In some of the cases moderate fever was present during the early course, which, as a rule, soon disappeared. The duration of the disease lasts many months. In the cases terminating fatally, death is as a rule due to the cardiac failure. In some instances it is due to paralysis of the diaphragm and bronchopneumonia, and in one case the cause was phthisis. The cases may be classified into four groups: (1) Those in which all the symptoms are marked; (2) those presenting skin lesions; (3) those showing prominence of the cardiac and hepatic symptoms; and (4) those presenting paralytic symptoms. If a careful history and examination be made, the diagnosis is easy. From the standpoint of treatment he sounds a note of warning as to the use of such depressing drugs as potassium iodid, sodium salicylate, antipyrin, exalgin, phenacetin, etc. After the poison has been stopped the treatment is symptomatic. Reynolds concludes the article with a review of previous epidemics and an analysis of his personal statistics. [F.J.K.]

5.—Buchanan in an article on **arsenical peripheral neuritis** gives the history of a number of cases presenting themselves at the Stanley Hospital, Liverpool. In nearly all of the cases a history of beer-drinking was obtained. Associated with the neuritis in many of the patients there were other symptoms common to arsenical poisoning. Buchanan concludes the article by saying that he felt it his duty to notify the Health Officer of the city, giving the names of the establishments from which the beer was purchased and the names of the patients. [F.J.K.]

6.—Moullin expresses great confidence in the **Röntgen-rays** as a diagnostic measure in cases of **urinary calculus**. If two careful examinations be made and no calculus found it may be taken as certain that none is present. In cases of fixed calculus he thinks this method the only one by which the presence of a calculus can be ascertained. In cases of ureteral calculus the rays are of the utmost importance. Before the picture is made the bowels should be thoroughly cleaned out, all clothing removed and the patient assume a recumbent position when the rays are applied. In renal calculi the movability of the kidney from respiration often renders the taking of a skiagraph difficult. In these cases a firm binder should be placed about the abdomen and the patient be asked to make shallow respiration. [J.H.G.]

7.—Cambridge has made very careful experiments with **urotropin** as a urinary antiseptic. He finds that the drug possesses no diuretic quality nor does it make any appreciable change in the excretion of a chemical constituent of the urine. The drug was found in the urine 10 minutes after a 10 grain dose was taken, and a small quantity was found 26 hours after the administration of the drug was discontinued. After 4 days of administration the patient complained a great deal of a sensation of formication. In experimenting with the germicidal qualities of urotropin he found that the strong solutions kill microorganisms, but the weaker solutions only inhibit their growth. The typhoid bacillus is very quickly destroyed by the drug, but the bacillus coli communis and the staphylococcus pyogenes aureus show considerable resistance. As formaldehyde in weak solutions kills B. coli communis it is not thought that the good effects produced clinically in cystitis by the administration of urotropin are due to the production of free formaldehyde, but rather to urotropin itself. From his experiments Cambridge concludes that urotropin alone may by prolonged heating be made to yield formaldehyde, but that this decomposition does not take place at the body temperature; that an alkaline solution of urotropin may be similarly decomposed, but the body temperature is not sufficient to cause the change; dilute acids quickly decompose urotropin on boiling with the evolution of free formaldehyde and that this change occurs to a less degree at 37° C.; acid salts—e. g. of the urine—liberate formaldehyde from urotropin on boiling, but not at 37° C.; that the acid urine of a person taking 30 grains of urotropin a day does not contain free formaldehyde. If the foregoing be correct an important point in securing the full effect of the drug would be that the urine should be acid when it leaves the kidney. This fact is borne out clinically in cases of typhoid cystitis where the drug is of particular use, since here the urine is usually acid. Cambridge urges that since the typhoid bacillus is demonstrable in the urine long after the disease has passed, that the administration of this drug would be of advantage both to the patient and the community at large. [J.H.G.]

8.—Elder reports a case of **infective parotitis** following abdominal section for appendicitis in a man, 20 years of age. The right parotid gland was involved 3 days after the operation. Thirty-six hours later the left gland was involved, during which time the swelling of the right had subsided. Intense pain and fever accompanied the swelling. Elder states that 49 days before the onset of the symptoms of parotitis, he treated the patient's brother for mumps. The brothers did not live in the same room until 9 days before the infection occurred. He concludes by saying that it is impossible to say whether the case was one of true mumps or parotitis following abdominal section. [F.J.K.]

9.—Clarkson reports a case of **gangrene of the penis** occurring in a man, aged 51 years, dying from arterial sclerosis. The gangrene was complete, was moist, and no local cause in the condition could be demonstrated. The patient's general condition was extremely bad, and he died without anything radical being done for his local condition. Clarkson refers to a case of dry gangrene which occurred at King's College Hospital in the service of Mr. Partridge. [J.H.G.]
